## Acknowledgments

This report presents findings of 'Livelihood Resilience in Dry Areas' (PN24), a project of the Consultative Group on International Agricultural Research (CGIAR) Challenge Program on Water and Food (CPWF). The authors would like to acknowledge the late Dr Mohsen Mohsenin's contributions. Also, Thanks are due to Dr Ahmed Hachum for his editorial work and Dr Sharam Ashrafi and Dr Nader Heydari, as the Basin Coordinators.

5.3.3. Advantages of SPI ..... 111
5.4. Methodology ..... 114
5.5. Results in Honam and Merek ..... 120
5.6. Spatial analysis of climatological drought ..... 121
5.7. References ..... 122
Appendices ..... 125

## Executive summary

The project - 'Strengthening Livelihood Resilience in the Upper Catchments of Dry Areas by Integrated Natural Resources Management' was undertaken in the Karkheh River Basin (KRB) of southwest Iran, from August 2005 to December 2008. The research program was guided by the 'Integrated Natural Resources Management' framework, in which assessment of water resources was one of the most important components. The KRB is a large basin with 47 plains and hydrologic units. This report presents an overall view of its surface water and groundwater status, together with two detailed case studies in Honam and Merek sub-basins.

The overall goal of the project was to strengthen livelihood resilience of the rural poor and to improve environmental integrity in the upper catchments of the basin. The data collected was being fed into new models of catchment management and policy.

The first chapter provides an analysis of annual runoff and annual runoff coefficients to explain spatial variation of surface water in the upper KRB. Runoff analysis is considered for different time scales and places. Runoff was analyzed in different types of basins under varying climates. According to the results, runoff depth has a relatively high correlation with precipitation and slope; however, in single variable analysis, it showed a greater correlation with slope than precipitation.

In the second chapter, a summary of hydrogeology and groundwater quality is presented for the KRB. Alluvial and karstic aquifers and their geological and hydrological properties are described. To prepare a general water balance for the basin, aquifers (alluvial and karstic), groundwater exploitation along with groundwater usage, balance, and quality are considered in the different hydrologic units. In addition, a water balance overview of the KRB is discussed that presents a schematic sketch of groundwater resources and uses in the basin.

Chapter three is devoted to the study of water assessment in Honam and Merek subbasins of KRB. Two hydrometric data loggers and a rain gauge installed/selected in each watershed are explained. For both catchments, a simple water balance equation is used in which the amount of rainfall is set equal to the sum of outlet discharge, evapotranspiration, and exchanging groundwater.

The application of a single rainfall-runoff event model for evaluation of land use effect on flooding in Honam and Merek is explained in chapter 4. GIS and HEC-HMS models are combined to assess the effects of different scenarios of land-use changes on runoff and hydrograph shape. The results emphasize the effects of land-use changes on hydrologic response of the basin. The simulation by HEC-HMS shows that unsuitable land-use would increase the peak flow and flood volume, whereas proper land use would decrease them.

In chapter five, drought in the upper KRB is analyzed using Standardized Precipitation Index (SPI). The index principles are reviewed and applied to the monthly precipitation data of the nearby stations of Kermanshah and Alashtar for, respectively, Merek and Honam for various time scales, i.e. 1-, 3-, 6-, and 12-month SPIs are used to evaluate hydrological and agricultural droughts. Using rainfall data (1966-2000), it is clear that Honam and Merek catchments experienced, respectively, 14 and 20 droughts of 1-3 months length. During 1966-2000, there was no drought in Honam in October, whereas

Merek experienced drought 11 times in that month. In November, the two catchments suffered very similar droughts, often at the same time. In both catchments, the frequency of drought in April was almost the same. Drought in May was more frequent in Merek than Honam, although in some years both catchments experienced drought in this month.

## Chapter 1.

## Runoff Analysis of the Upper Karkheh River Basin

 Jahangir Porhemmat, Adriana Bruggeman and Bagher Ghermezcheshmeh
# Chapter 1: Runoff Analysis of the Upper Karkheh River Basin 

### 1.1. I ntroduction

The Karkheh River is located in southwest Iran with elongated tributaries to the central part of the country. It originates from high mountains in the north west of Iran and terminates at Hour-Al Azim on the Iran-Iraq border with south. It is completely situated in Iran, with only the outlet at the political borders.

The KRB has a wide range of climates due to the high Zagros Mountains in the upper part, with cold and relatively wet zones, and the Khoozestan Iowland plain on the lower part with a hot and arid-semi-arid climate at the outlet. The Karkheh highlands and rugged terrain on the upper part receive considerable precipitation as rain or snow in the mountainous parts, where the river tributaries originate with permanent streams that eventually join to form the Karkheh River. There are different hydrological characteristics and units in the upper part of the basin due to inter-mountainous plains forming many catchments with different hydrological behaviors, which require much data and information for assessment of water resources and water allocation. Although there are many gauging stations in the basin, there are a limited number of such stations at the catchment scale and only a few are gauged. Water scarcity is a dominant problem in KRB dry areas, and so for water resource management and planning, a detailed assessment of water resources and their spatial and temporal distribution is needed, at least, at catchment level. This report provides an analysis of annual runoff and annual runoff coefficients to explain spatial variation of surface water in the upper KRB.

### 1.2. Materials and methods

### 1.2.1. General geography and physiographical setting of the KRB

The KRB is one of the second-order basins of the Persian Gulf and one of the six first-order or major basins of Iran located in south west of the country (Jamab, 1999). Figure 1.1 shows the location of the KRB on the Iranian side of the Persian Gulf Basin. All highlands of this basin are in the Zagros Mountain range, spread over the north and northeastern to eastern areas of the

Figure 1.1. Location and the main basin of the KRB in Iran.

Table 1.1. Characteristics of main sub-basins of the KRB.

| Sub-Basin | Area <br> $\left(\mathbf{k m}^{2}\right)$ |  | Min <br> elevation (m) | Mean <br> elevation (m) | Max <br> elevation (m) |
| :--- | ---: | ---: | :--- | :--- | :--- |
| Saymareh <br> at Holylan | 19977 | 911 | 1748 | 3598 | 17.6 |
| Kashkan at <br> Pol e Dokhtar | 9267 | 659 | 1632 | 3615 | 22.4 |
| KRB at <br> Paye Pol (Dam) | 42191 | 97 | 1544 | 3615 | 19.3 |

basin, and elevation is reduced in the western and southern parts of the basin. The highest point elevation of the KRB is 3645 m above mean sea level. The KRB extends over $51806 \mathrm{~km}^{2}$, which is $3.2 \%$ of Iran, and has a perimeter of 1891 km . KRB is located within $30^{\circ} 49^{\prime}-34^{\circ} 04^{\prime} \mathrm{N}$ and $46^{\circ} 06^{\prime}-49^{\circ} 10^{\prime} \mathrm{E}$. The main river tributaries of the upper KRB are the Saymareh and Kashkan Rivers and a mid-basin. The Saymareh River is in the western part and is formed from two subbasins: the Gamasiab and Gharesoo.

Figure 1.2. DEM of the KRB (Source: SCWMRI).

Table 1.1 shows the general characteristics of three main parts (main sub-basins) of the upper KRB. The upper KRB is mountainous areas with different elevations (Figure 1.2). Based on the Digital Elevation Model (DEM) of the KRB (Figure 1.2), the upper KRB ranges in elevation from a few meters to 3645 m above mean sea level. Slopes are varied over different parts of the basin (Figure 1.3). The aspect map of the upper basin (Figure 1.4) was computed using the DEM.

Figure 1.3. Slopes of the upper KRB (source: SCWMRI).

Figure 1.4. Aspect map of the upper KRB (extracted from DEM).

Figure 1.5. Elevation classes (hypsometry) of the upper KRB.

### 1.2.2. Data collection and processing

The general information needed for surface flow analysis is physiographic, climatic, and discharge from the hydrometric stations.

Physiographic data and information needed for the above analysis can be used from other sections of this report. The DEM of the basin was prepared from digital contour lines of a topography map (1:250 000). Area-elevation classes (hypsometry) were computed for each KRB sub-basin corresponding to hydrometric stations using the DEM of the basin. Table 1.2 shows the general characteristics of the hydrometric stations in the upper KRB. Table 1.3 shows the hypsometry for the selected hydrometric stations in the upper KRB.
Figure 1.5 shows elevation classes corresponding to the upper KRB (as well as Pay-e pol from the lower KRB).

Figure 1.6. Distribution of rain gauges in the upper KRB.

Table 1.2. Selected hydrometric stations for surface water analysis in the upper KRB.

Runoff coefficient analysis utilized monthly and annual precipitation data. Precipitation is monitored by two organizations in Iran: the Metrological Organization of Iran (MOI) and the Water Office of the Ministry of Energy (MOE). As the data of the latter are distributed corresponding to hydrometric stations and at basin scale, the rain gauge data of the water office was used in this study. Table 1.4 shows the geographic
coordinates and Figure 1.6 shows the locations of the rain gauge stations in the KRB.

Climate is an important factor in controlling water resources. The climate map used in this study (Figure 1.7) was a version prepared by Soil Conservation and Watershed Management Research Institute (SCWMRI). The KRB has a range of different climates based on SCWMRI
Table 1.3. Area ( $\mathrm{km}^{2}$ )-elevation (m) classes (hypsometry) for selected hydrometric stations in the upper KRB.

reports: a wide range of arid to wet. Approximately 50\% of the KRB area up to the dam site has an arid climate, which includes the lowest part of the upper KRB completely (Table 1.5). Wet and semi-wet climates cover 27\% of the KRB area up to the dam. Areas of arid climate in the Saymareh sub-basin represent $18.3 \%$ of the KRB area up to the dam site. Thus, this sub-basin is drier than the other two sub-basins, namely the Kashkan and the mid-basin.

Raw data of discharge at hydrometric stations was used from SCWMRI reports on characteristics of basins in Iran. The data were checked and tested by conventional methods in the data processing stage in the SCWMRI reports, e.g. by using run test and double mass curve. Only 27 stations in the upper KRB had sufficient data and 78 stations did not. Figure 1.8 shows the geographical distribution and locations of the hydrometric stations in the upper KRB. Table 1.6 shows the main physiographic parameters of the hydrometric station basins in the KRB using DEM, slope, and aspect digital maps.
Regression analysis was used to fill missing data or for completion of timeseries by selection of the stations with data for the whole period. Data of water years (Iranian calendar) of 1349-1350
(corresponding to 1970-1971) to 13781379 (corresponding to 1999-2000) was used for the analysis for timeseries of discharge and precipitation (SCWMRI, 2006). Table 1.7 shows the regression relationships between hydrometric stations with missing data and the stations with complete data, as suggested by SCWMRI (2006). Timeseries were completed using Table 1.7 formula and the observed data in the selected 27 stations. Data processing results were used to compute mean 30-year annual discharge (Table 1.8), which can be considered a consistent time-series for hydrologic components (SCWMRI, 2006).

### 1.2.3. Precipitation

Spatial distribution of mean annual precipitation for the upper KRB was needed to determine spatial distribution of runoff. This analysis was done based on the point mean annual precipitation obtained from the observed data. The 30-year mean annual precipitation was computed using monthly precipitation records of the Water Office of MOE (Tamab Company) and the results are shown in Table 1.9 for 40 rain gauge stations (SCWMRI, 2006). Figure 1.6 shows the distribution of the rain gauge stations used in spatial analysis of precipitation in KRB (Table 1.9).

Table 1.5. Areas of different types of climate in the three main sub-basins of the upper KRB.

| Basin | Area (km²) |  |  |  | Area (percent of whole KRB at dam) |  |  |  |

Figure 1.9 is the result of spatial analysis of annual precipitation in the region and shows the isohyets derived from a combination of geostatistical and regression analyses. Mean annual precipitation over every individual subbasin was achieved by classifying isohyets (Figure 1.10), and shows that the KRB has a wide range of precipitation with a decreasing trend from north to west in general. However, there are spatial variations in different parts corresponding
to mountainous belts such as the
northeast and southwest (Figures 1.9 and 1.10). The mean annual precipitation for the three main sub-basins of the KRB varied from 490 to 556 mm (Table 1.10).

### 1.2.4. Modeling of runoff generation at regional scale

Regional analyses are used in peak discharge analysis by a number of researchers and are used widely for

flood peak assessments in un-gauged catchments. Different methods of regional analysis have been suggested, with regression models considered the soundest of choices. Regression models use flood peaks as dependent parameters and the available physical and climatic parameters as the variables. Areas, shape factors, elevation components, and slopes are the physical parameters used in regional regression modeling; and precipitation, temperature, and water deficit are the main climatic parameters used.

Peak flow is an important index of floods and surface runoff from flooding. Regional analyses were carried out for peak flow analysis based on the physical and available climatic data. The area, the 30-year annual mean runoff, and precipitation were used as the independent variables in the present study, and the peak discharge was the dependent variable.

### 1.3. Results of runoff regional analysis

### 1.3.1. Runoff contribution of the subbasins

Table 1.8 shows the 30 -year mean annual flows for different tributaries in the upper KRB up to the dam site (Pay-e pol station is situated just a few kilometers downstream of the dam outlet and is considered the lowest point in the runoff analysis). In addition, Table 1.9 shows the 30-year mean annual precipitation for the different tributaries in the upper KRB.

The spatial mean annual discharge map and the corresponding spatial mean annual precipitation map were derived using mean annual data presented in the previous sections. Figure 1.10 shows the results as digital maps of mean annual runoff and precipitation depth for each sub-basin in the upper KRB, respectively.

Based on Figure 1.10 and Table 1.8 data, runoff discharge increases from the upper to lower parts, except in the upper Gamasiab basin where Sange Soorakh has less discharge relative to Goosheh Saad (situated in the lower part and

drains Sange Soorakh). This anomaly is due to water consumption in the mid part between these two stations. A key value to compare runoff generation level of each catchment is the runoff depth instead of runoff discharge. The runoff depth was computed for each catchment or sub-basin from discharge and area in Table 1.8. Table 1.11 shows the depth of runoff and precipitation with other basin parameters used in regional analysis for each hydrologic unit. Runoff generation varied between 35.5 mm in Shahab catchment at Aghajanbolaghi station in the upper Gamasiab to 541.5 mm in Abzal catchment at Pol-e Zal station in the upper Kashkan River. The maximum runoff in the catchments is 15.3 times more than the minimum, and the minimum is $20 \%$ of the arithmetic mean of the 27 sub-basins. These results show a high variation in runoff generation in the upper KRB.

In addition, Table 1.11 shows the contribution of the main sub-basins in runoff generation. Overlaying Figures 1.9 and 1.10 shows the variation of mean annual precipitation and the corresponding basin runoff in different sub-basins from upper to lower parts of the KRB. The two main sub-basins of the upper KRB are Saymareh and Kashkan, which represent 69.3\%, Table 1.8) of the upper KRB in both Saymareh at Holylan and Kashkan at Pol-e DokhtarTogether, Gamasiab and Gharesoo are the main upper sub-basins. The runoff depth at Ghoorbaghestan and Pol Chehr are,
respectively, 143.3 mm and 111 mm , which shows that runoff generation in Gharehsoo is 1.3 times larger than in Gamasiab.

Khorramabad and the upper Kashkan are the main two sub-sub-basins of Kashkan sub-basin, with areas of 1630 and $6842 \mathrm{~km}^{2}$ at Chamanjir and Afrineh, respectively, and both have similar runoff generation: 223 mm for Chamanjir and 222 mm for Afrineh. Thus, there is little difference in runoff generation between the main sub-sub-basins of Kashkan subbasin (Table 1.8).

Kashkan and Saymareh have considerable difference in runoff generation. Kashkan at Pol-e Dokhtar has $16.5 \%$ and Symareh at Holylian has $40 \%$ of upper KRB runoff.

### 1.3.2. Modeling of runoff generation at regional scale

## Mean annual runoff analysis

Mean annual runoff analysis was done by using physical and climatic parameters. Area, slope, and precipitation are the parameters used in regional analysis of mean sub-basin runoff. Table 1.12 shows the results of regional regression analysis of runoff depth. Correlation coefficients varied from 0.693 to 0.772 for different models. Runoff depth was more highly correlated with two parameters (precipitation and slope) compared to one parameter (slope). Slope, as a single variable, had the highest correlation relative to the other parameters (area and precipitation).

Table 1.12. Results of regional regression analysis of runoff.

| Model | R | MAE* |
| :--- | :--- | ---: |
| Runoff $=(11.809 \times \mathrm{S})+(0.517 \times \mathrm{P})-284.23$ | 0.772 | 60.96 |
| Runoff $=(15.455 \times \mathrm{S})-123.54$ | 0.693 | 74.94 |
| Karkheh at Paye- Pole | 262 | 731 |
| Karkheh at dam | 262 | 785 |

[^0]Table 1.13. Regression models for runoff discharge and hydrological parameters.

| Row | Regression relationship | Regression coefficient | No of samples |
| :--- | :--- | ---: | ---: |
| 1 | $Q=-14.78+(0.00423 \times \mathrm{A})+(0.0299 \times \mathrm{P})$ | 0.99 | 27 |
| 2 | $\mathrm{Q}=(0.0042 \times \mathrm{A})+1.69$ | 0.99 | 27 |
| 3 | $\mathrm{Q}=0.0342 \times \mathrm{A}^{0.76}$ | 0.85 | 27 |
| 4 | $\mathrm{Q}=26.958 \mathrm{Ln}(\mathrm{A})-170.4$ | 0.79 | 27 |
| 5 | $\mathrm{Q}=5.4751 \mathrm{e}^{9 \mathrm{EE-05} \times \mathrm{A}}$ | 0.83 | 27 |

Note: Q is runoff (stream flow; $\mathrm{m}^{3} / \mathrm{s}$ ), A is area $\left(\mathrm{km}^{2}\right)$, and P is precipitation (mm).

Table 1.13 shows regression models for runoff discharge (instead of runoff depth) and hydrologic parameters. Regression coefficients varied from 0.79 to 0.99 for different models. The highest correlations between different parameters were due to both the linear model with two variables (first row in Table 1.13), and the linear model with single variable (second row in Table 1.13). As precipitation has a key role in runoff generation and the twovariable model had the same regression coefficient as the single variable, the two-variable models for runoff depth and runoff discharge were selected as a regional model for un-gauged catchments in the KRB. The selected equations are as below, based on the two methods:
$R d=(11.809 \times S)+(0.517 \times P)-284.23$
$Q=-14.78+(0.00423 \times \mathrm{A})+(0.0299 \times \mathrm{P})$
Where, Rd is mean annual runoff depth ( mm ) , Q is runoff discharge, P is mean annual precipitation ( mm ), S is slope (\%), and A is the area of the basin ( $\mathrm{km}^{2}$ ). Equation (1) is for the condition in which mid sub-basin runoff depth is needed, and equation (2) is for when discharge of the whole basin is needed.

### 1.3.3. Regional peak flood analysis

Peak flood is an important index of floods, because it represents the maximum capacity of flood generation by events. Flood peak analysis has been done by SCWMRI in a project entitled 'Characteristics of Watersheds of Iran'.

The results showed that mean daily flood peaks and instantaneous peaks had a high interdependence and the daily peaks had a high correlation with 30 -year mean annual discharge. The 30 -year mean annual parameters are some available components used in the regional analysis and are consistent parameters. Figures 1.11 to 1.16 show the relationship of daily peaks to the 30 -year mean annual discharge for $2,5,10,25,50$, and 100-year return periods, respectively (SCWMRI). Table 1.14 shows different regression models for different return periods of the maximum daily discharge with the 30-year mean annual discharge. The regression coefficients ranged from 0.8 to 0.96 for the different models in the above return periods. For example, the exponential equation for 100-year return periods had the minimum regression coefficient but the linear equation of the two-year return period had the maximum coefficient. The best fitted model for each return period was selected based on the above criteria. For example, the selected model for the two-year return period is as below:
$\mathrm{Q}_{\mathrm{m}}=10.051+7.2853 \mathrm{Q}$
Where, $\mathrm{Q}_{\mathrm{m}}$ is maximum daily discharge with a return period of two years and Q is the 30 -year mean annual discharge, both in $\mathrm{m}^{3} / \mathrm{s}$. The selected model for each return period is shown in Table 1.15 by a star notation.

| 21 | 0.85 | Qm = 1019Ln(Q) - 1677.3 | 100 |

Note: $1-Q_{m}$ is maximum daily discharge with a return period and $Q$ is the mean 30 -year annual discharge, both in $\mathrm{m}^{3} / \mathrm{s}$ 2-* selected model for the region

Instantaneous peaks are closely related to maximum daily discharge; therefore, regression analysis was used for extracting equations in SCWMRI (2006). The analysis was based on peak components, obtained by statistical analysis of the observed instantaneous and maximum daily peaks for different
return periods. Table 1.15 shows the regression models for different return periods of instantaneous flood peaks with maximum daily discharge. Maximum instantaneous peak flow for some hydrologic units in the KRB was estimated using Table 1.15 equations, and gave the results of estimated maximum daily

discharge and instantaneous peaks based on 30-year mean annual discharge for these sub-basins in the upper KRB (Table 1.16).

### 1.4. Conclusion

Runoff analysis was considered for different time scales and places. Semispatial distribution of runoff was analyzed in different sizes and types of basins and in different types of climate. Runoff, as an index of depth of water in sub-basins, is needed for un-gauged basins which may have data of discharge or runoff in some part of the basin, i.e. some midbasins that are not gauged. Peak flow is an important index of floods and was considered in the regional analysis of the present study. The results are as follows:

1. Runoff depth had a relatively high correlation with precipitation and slope; however, in single variable analysis, it showed a greater correlation with slope than precipitation. Although the first behavior is normal, the second needs more attention in future studies.
2. Runoff discharge in large basins had a high correlation with precipitation and area in multiple regression analysis, but only with area in single variable regression. This is normal behavior, because when area is the input for outflow as a single variable, as the basin gets larger, the contribution of
the basin to outlet discharge increases proportionally to increasing area.
Such behavior shows that regional analysis results could apply to the same regions, but to avoid omission of the role of major inputs - in this case precipitation - the small to medium sized basins should be considered in regional regression analysis.
3. Peak discharges show different behavior relative to time scale. Daily peak discharge was correlated with mean annual discharge, but instantaneous peak discharge was not. Finally, the instantaneous peak discharge was significantly correlated with daily peak discharge. Such behavior shows an interrelationship between time scales of runoff discharge in which, with increases in time base for outflow discharge, the stability of the relationship between mean discharges over period increased.

# Chapter 2: Groundwater in the Karkheh River Basin 

Jahangir Porhemmat, Adriana Bruggeman and Pyman Daneshkar Arasteh

### 2.1. Introduction

The Karkheh River Basin (KRB) is located within $30^{\circ} 49^{\prime}-34^{\circ} 04^{\prime} \mathrm{N}$ and $46^{\circ} 06^{\prime}-$ $49^{\circ} 10^{\prime} \mathrm{E}$ in southwestern Iran (Figure 2.1). The basin is a second-order basin belonging to one of the six first-order basins of Iran, namely, the Persian Gulf Basin. The highlands of the KRB are part of the Zagros Mountain range that spreads over the north and northeastern to eastern areas of the basin, with gradual decreases in elevation in the western and southern directions. With its highest elevation at 3645 m above mean sea level, the KRB covers $51806 \mathrm{~km}^{2}$, which is $3.2 \%$ of Iran's total area, and has a perimeter of 1891 km . The area of the basin upstream of the Karkheh Dam is $42191 \mathrm{~km}^{2}$.

The main tributaries of the Karkheh River in the upper KRB are the Saymareh and Kashkan Rivers. The Saymareh River runs in the western part and is formed by the confluence of two smaller streams, the Gamasiab and Gharesoo Streams.

Study of hydrogeology and hydrogeochemistry of a basin groundwater is one of the first and important activities needed in a river basin water management program. In the present report, a brief summary of hydrogeology and groundwater quality is represented for the KRB. Alluvial and karstic aquifers and their geometrical and hydrological properties are described.

### 2.2. Methodology

According to Jamab (1999), there are 47 recognized 'study area' units within the KRB with hydrogeological study
and geophysical measurements. These study areas were named by Jamab (1999) in all the plains, together with the corresponding surface hydrologic units. In effect, any such study area is a watershed or hydrologic unit. Table 2.1 shows those units and their area and codes. The area of the KRB plains is about $22571 \mathrm{~km}^{2}$, which covers the above 47 study units (Figure 2.1).

Following the launching of Livelihood Resilience project in the KRB, hydrogeological studies were started.

For this purpose, many reports and data were gathered and reviewed, of which the Comprehensive Water Plan prepared by Jamab (1999) was the most complete and accordingly much of our information needs were taken from this document.

Study of the hydrogeology of the KRB included groundwater resources, especially aquifers (both alluvial and karstic), springs, and qanats as well as all water uses in different sectors. In order to prepare a general water balance for the basin, aquifers (alluvial and karstic), groundwater exploitation, groundwater usage, groundwater balance, and groundwater quality were considered in the different hydrologic units. Finally, based on the available data, a water balance overview of the KRB was prepared, which presents a schematic sketch of groundwater resources and uses in the basin.

### 2.3. Groundwater characteristics

### 2.3.1. Aquifers

There are more than $9382 \mathrm{~km}^{2}$ of unconfined aquifers within the 47 study areas, but the area of the confined aquifers is unknown. Area of the aquifers increases southward, but aquifer thickness and transmissivity decreases. Groundwater quality of northern part of the KRB is better than in the southern part. Aquifer thickness varies from 300 to 15 m southwards. The highest aquifer transmissivity is about $2000 \mathrm{~m}^{2} / \mathrm{d}$ for the study areas 1, 2, 4, 11, and 41. Table 2.2 shows the geometric and hydraulic properties of the 47 unconfined aquifers of the KRB, among which, groundwater elevation isopiece maps and unit hydrographs of water table fluctuations are provided for only 15 aquifers. There are 411 springs with an annual discharge of about $59 \mathrm{Mm}^{3}$ in these unconfined aquifers.

### 2.3.2. Hard formations

The area of hard formations in the KRB is about $28193 \mathrm{~km}^{2}, 36 \%$ of which is covered by karsts. There are more than 2335 karstic springs in the KRB with a total annual discharge of $1815 \mathrm{Mm}^{3}$. Table 2.3 summarizes the characteristics of some of these springs and Table 2.4 shows the properties of the wells dug in the hard formations.

### 2.3.3. Groundwater exploitation

There are 16057 groundwater abstraction sources in KRB with an annual water production of about $3.778 \mathrm{Bm}^{3}$. Among these resources, 11901 wells discharge a total amount of $1.581 \mathrm{Bm}^{3}$. Table 2.5 shows discharges of different types of groundwater sources in KRB. There are 1410 qanats and 2746 springs with annual discharges of 0.17 and 1.874 $\mathrm{Bm}^{3}$, respectively.

### 2.3.4. Groundwater usage

The annual demand for groundwater in KRB is about $1.657 \mathrm{Bm}^{3}$ with agricultural
needs consuming 87.6\% of this total. Table 2.6 shows the water demands and requirements in agriculture, industry, and domestic divisions.

### 2.3.5. Groundwater balance

Groundwater balance components (Table 2.7) were determined according to the hydro-climatological water balance method (Figure 2.2).

### 2.3.6. Groundwater quality

Groundwater quality is very variable in the KRB. Table 2.8 shows the results of primary analysis of the groundwater samples. Quality classifications of groundwater for agricultural and domestic uses are shown in Tables 2.9 and 2.10, respectively.

# Chapter 3: Water Resources and Balance of Honam and Merek Catchments 

Jahangir Porhemmat, Adriana Bruggeman, Majid Heydarizadeh, Iraj Veyskarami, Homayoon Hessadi and Bagher Ghermezcheshmeh

### 3.1. Introduction

Water resources are among the most important components in assessing the potential of basins/catchments and their environment in planning for Integrated Natural Resources Management (INRM). To this end, comprehensive assessment of water resources and floods, and water productivity analysis in the Karkheh River Basin (KRB) was considered a priority component in the CPWF project. The large area of KRB was a parameter that limited availability of data and accuracy of achieving results. Honam and Merek, as small basins (catchments), were chosen for collection of detailed data on water resources and water balance to be used in water resources managements. The purpose of this research was to assess the water balance and water resource for these two catchments that had no currently available data. Therefore, it was necessary to collect some data in the research stage to estimate the indices of the relationship between the catchment and basin behaviors.

The ability of water balance models to incorporate monthly or seasonal variations makes them especially attractive for water resource studies and management. The use of conceptual models has increased in recent years and it is likely that computer simulation of catchments will increasingly be used by, and for, water resource managers as an aid to decision making. Different hydrological models have also been developed to account for the changes in physical processes associated with different land use and climate changes, which in most of the early models were lumped and statistical.

A distributed conceptual model, the Darling Range Catchment Model (DRCM), was developed and applied to some catchments in the Darling Range of Western Australia (Mauger, 1986). Sivapalan et al. (1996) simplified the conceptual form of DRCM and developed the Large Scale Catchment Model (LASCAM). This model was tested, calibrated, and validated across a range of different catchments, from small experimental to very large (Sivapalan et al., 2002). TOPOG (Vertessy et al., 1993) and WEC-C (Water and Environmental Consultants-Catchment) are two other fully distributed models that are applicable to hill slopes and experimental scales (Croton and Barry, 2001). Although distributed hydrological models are applied all over the world, it is now well understood that the basic limitations of these models to simulate catchment responses with a small number of parameters is due to their inability to reproduce dynamic variation of saturated areas within the catchment (Beven, 1989; 2001; Binley et al., 1989). In fact, the dynamic variation of the saturated area, a function of accumulation and horizontal movement of water in the top soil layers, is mainly responsible for the highly nonlinear nature of catchment response to storm events (Ruprecht and Schofield, 1989; Todini, 1996). Most of the existing conceptual and semi-distributed models require a large number of parameters to represent dynamic variation. Many of these parameters lack physical meaning since they represent averages of the catchment or sub-catchment characteristics.

Recent studies have only been devoted to water balance prediction of steadystate catchments. The monthly water
balance model WASMOD was developed for water balance computation for the NOPEX region (Xu et al., 1996; $\mathrm{Xu}, 2002$ ). The model parameters are related to the physical characteristics of the basins (Xu, 1999). The input data for using the model on gauged basins are monthly areal precipitation, potential evapotranspiration, and/or air temperature. To use the model on un-gauged basins, land use and/or soil distribution data are needed. The model outputs are monthly stream flow and other water balance components such as actual evapotranspiration, slow and fast components of stream flow, soil-moisture storage, and accumulation of snowpack.

Another model is the Salas model - a simple watershed model for annual and monthly stream flow simulation (Salas, 2002; Laurel et al., 2008). This model assumes a single watershed or lumped basin (not dividing the watershed into sub-watersheds), and the temporal scale is an annual period. The model can also be applied to a season, depending on the particular case. The variables in the hydrologic cycle of the watershed that occur during the time interval $t$ are mean precipitation (P1) over the basin, surface runoff (SR1), infiltration (It), actual evapotranspiration (It), deep percolation (DPt), base flow (BFt), groundwater flow (GFt), groundwater storage at the beginning of the time interval $t$ (GSt1), and stream flow at the outlet of the watershed (Qt). The model assumes only one storage (reservoir) - the groundwater storage (GS) - this is an important component of the model where water is stored and released depending on the reservoir's inflows and outflows. The conceptual model of the watershed is made up of a number of simple models representing the various processes such as surface runoff, infiltration, evapotranspiration, deep percolation, base flow, groundwater flow, and stream flow. The model(s) essentially routes the
precipitation, Pt , through the watershed down to the basin's outlet. The watershed model is quite simple and expresses both the groundwater storage and the streamflow explicitly as a function of precipitation and the model parameters $\mathrm{a}, \mathrm{b}, \mathrm{c}$, and d - these four parameters must be estimated based on historical precipitation and streamflow data. For this purpose a trial and error procedure can be utilized or more sophisticated methods based on optimization techniques.

The abovementioned models need to have several years of data; however, there is no more than one year of data for Honam and Merek catchments. For these catchments, a simple water balance equation was used. In this equation, the amount of rainfall is set equal to the sum of outlet discharge, evapotranspiration, and exchanging groundwater table.

### 3.2. Materials and methods

### 3.2.1. Site selection

In 2006, the report 'Water resources monitoring site selection report for Merek and Honam' was published (Anonymous, 2006). Merek and Honam catchments are two sub-basins of the KRB (Figure 3.1). These two sites were studied and particular locations selected and equipped with data loggers, stages, and rain gauges, in the first year.

## General features of Honam

Honam watershed is part of the Alashtar River basin at Sarab-e Seyedali hydrometric station located within $49^{\circ} 08^{\prime} 00^{\prime}-49^{\circ} 17$ ' $35^{\prime} \mathrm{E}$ and $33^{\circ} 30^{\prime} 15^{\prime}$ $33^{\circ} 37^{\prime} 11^{\prime} \mathrm{N}$. The area of the basin is $140.16 \mathrm{~km}^{2}$, and average elevation is 2051 m above mean sea level, with the highest point at 3560 m above mean sea level in the east and the lowest point 1480 m above mean sea level in the western part at the basin outlet.

Figure 3.1. Geographical location of Honam and Merek catchments in the KRB, Iran.

The recorded data at Alashtar Meteorological Station was used to investigate Honam temperature and rainfall variations. The average annual temperature is $10.80^{\circ} \mathrm{C}$, with a minimum average temperature of $2.70^{\circ} \mathrm{C}$ in J anuary and maximum average of $20.80^{\circ} \mathrm{C}$ in July. The average annual rainfall of the catchment is about 690.5 mm .

Villages in Honam catchment include Presk-Bala, Presk-Paein, Honam, Berdbel, Chahar Takhteh, Jahanabad, Yariabad, Lamdar, Kolah-hil, Hajiabad, Shirabad, J afarabad, Noorabad, Karamolahi, Farajolahi, Aadelabad, Siahposh, and Espej. Figure 3.2 shows the drainage system and villages in Honam basin.

Figure 3.2. Drainage system and villages in the Honam basin.

## General features of Merek

Merek is a sub-basin of the KRB. Figure 3.1 shows the geographical location of Merek catchment in Iran and the KRB. Figure 3.3 shows the drainage system in Merek catchment.

Merek basin is a part of the Gharesoo River, and is a sub-basin of the KRB, located within 47004'52"-47022 $09^{\prime \prime} \mathrm{E}$ and $34000 \prime 25^{\prime \prime}-34014^{\prime} 05^{\prime \prime} \mathrm{N}$. The area of the basin is $305 \mathrm{~km}^{2}$. The highest point is 2774 m above mean sea level in the northeast part of the basin and the lowest point is 1483 m above mean sea level at the outlet in northwest part of the basin. Merek is a part of Mahidasht plain in the southwest of Kermanshah Province of Iran. Based on data of the Mahidasht Meteorological Station in the west
border, the climate of Merek is semi-arid according to De-Marton classification.

Table 3.1 shows the temperature components in Mahidasht Station, a climatological station adjacent to Merek basin. Temperature data of 1971-2003 show that the minimum and maximum monthly average temperatures were, respectively, $0.70^{\circ} \mathrm{C}$ in February and $25.30^{\circ} \mathrm{C}$ in July.

The average annual rainfall during 1966-2001 was 357 mm . Seasonal variation of precipitation represents a Mediterranean climate with a distinct winter and summer. Precipitation in autumn, winter, and spring is 30,45 , and $25 \%$ of the annual total, respectively, with insignificant precipitation in summer.

### 3.2.2. Data collection and measurements

There are different ways to express hydrological parameters, e.g. monthly and annual precipitation depth or flow discharge rate. The precipitation was measured by rain gauge and stream flows were measured by hydrometric instruments. Data of the existing recorder rain gauge in Alashtar synoptic meteorological station and data of the Presk standard rain gauge in Honam catchment were collected and used. In the case of Merek, a weighing recorder rain gauge was installed in the middle of the basin (Najafabad village) in May 2007 and the data were recorded. Hydrometric stations were established for measuring stream flow discharge. Spring and well discharges were monitored by personnel of the Ministry of Energy.

## Precipitation

a- Honam catchment
Data of monthly precipitation are necessary to determine water balance in any basin. In the present study,
data of the Alashtar Synoptic Station and Presk rain gauge station were used to determine the precipitation pattern in Honam catchment. This requires an adequate number of rain gauges to evaluate spatial variation in precipitation and its role as a major input for assessment of the basin water balance. There were nine standard rain gauges installed by the Meteorological Organization of I ran and local water office of Ministry of Energy within approximately 100 km of Honam basin. Table 3.2 shows the geographical coordinates of those rain gauges located at Chamanjeer, Khorramabad, Kaka Reza, Sarab Seyed Ali, Zaghe Khoramabad, Noorabad, Vanaie, Presk, and Alashtar. Records of these stations were considered for spatial analysis of the basin precipitation. Among these nine stations, Presk had a short history of data and the Khorramabad and Chamangeer stations were not used in spatial analysis due to weak correlations with other stations and being far from them. The relationship between mean annual precipitation and elevation was chosen for spatial analysis.

An annual regional precipitation equation was derived as follows:

$$
\begin{equation*}
P=(0.431 \times H)-150 \tag{1}
\end{equation*}
$$

Where, P is the mean annual precipitation ( mm ) and H is elevation ( m above mean sea level). For the above regression equation, the coefficient of determination $\left(R^{2}\right)=0.97$, which was significant at $95 \%$ level. Figure 3.4 shows the location of the stations situated inside and outside of the Honam basin within a distance of 15 km .

## b- Merek catchment

There were no automatic recording rain gauges in the Merek catchment; however, five standard rain gauges, installed by Iranian Meteorological Organization, were operational. A weighing rain gauge was installed by this project in the middle of the basin (Najafabad village) in May 2007. Table 3.3 and Figure 3.5 show the
geographical coordinates and locations of the rain gauges.

Table 3.4 shows the monthly and annual precipitation in the abovementioned stations from April 2007 to March 2008. The Najafabad station data are not shown due to lack of data for the whole period.

## Streamflow discharge

a- Honam catchment
Annual and monthly stream flow water level was measured by limnograph and stage in Zirtagh, and by limnograph and critical flume with stage in Presk hydrometric station. During normal days, water level shown by the stage was observed daily at noon. However, during rainy and flood periods, critical flume discharge measurement was made at hourly intervals. Table 3.5 shows the geographic coordinates and location of the hydrometric stations.

Figure 3.4. Location of Honam basin and standard rain gauge stations.

## Zirtagh station

Earlier in our study, a bridge on Khorramabad-Alashtar main road at the outlet of Honam catchment was selected as the site for installing the stagelogger water level meter; however, the installation was destroyed by Alashtar Road Bureau for widening the road. Additionally, this selected site did not include the entire basin area. A new site, downstream near Zirtagh village, was selected with geographic coordinates $48^{\circ} 18^{\prime} 41.46^{\prime \prime} \mathrm{E}$ and $33^{\circ} 48^{\prime} 23.29^{\prime \prime} \mathrm{N}$, at the outlet of the basin and included the whole basin. Figure 3.6 shows a view of the instruments including derricks, telepheric bridge, and stage-logger water level meter. The daily data of the stage were available from 15 February 2006; and for the stage-logger, data with $2-\mathrm{h}$ interval were available from 17 April 2007. The
water level recorder use was Global Water Level Meter 9" Model provided by CP project funds. A discharge (Q)-stage (H) curve was prepared for the sites (Figure 3.7) using the measured discharge and corresponding stage at different water levels (Table 3.6).

## Presk station

Upstream of Honam catchment, there is a karstic spring called Presk that forms the main part of the base flow of Honam River. A diversion dam at the coordinates $48^{\circ} 24^{\prime} 34.67^{\prime \prime}$ E and $33^{\circ} 48^{\prime} 23.29^{\prime \prime} \mathrm{N}$ was constructed to supply water for Presk village farms and a fish pond. A supercritical flume (Figure 3.8) equipped with a Global Water Level Meter 9" Model data logger was built upstream of the diversion dam - the data were available from 17 April 2007.

Table 3.6. Stage and related discharge of Zirtagh hydrometric station.

Figure 3.8. View of the supercritical flume installed in Presk spring.

## Spring discharge

There are 19 springs in Honam watershed, including the permanent and important Honam and Presk springs. Therefore, hydrometric equipment was
installed in these streams. Figure 3.9 and Table 3.7 show the geographical coordinates, mean annual discharge, and annual volume of all springs in Honam watershed.

## Honam spring

A spring called Honam is located in the middle of the catchment, at $48^{\circ} 18^{\prime} 43.83^{\prime \prime}$ E and $33^{\circ} 48^{\prime} 24.83^{\prime \prime} \mathrm{N}$, and has a considerable discharge. The local water office monitors the spring and collects data in monthly periods. Figure 3.10 shows the outlet of the Honam spring with its stage. Discharge of the Honam spring was measured from 17 April 2004. Total discharge and use of Honam spring water amounts to $57.43 \times 10^{6}$ and $29.75 \times 10^{6} \mathrm{~m}^{3} /$ year, respectively.

Figure 3.10. View of Honam spring (left) and the stage used for measuring its discharge (right).

Diversion intakes for the main irrigation channels
There were 28 diversion intakes used for taking irrigation water from Honam River. Figure 3.11 and Table 3.8 show their locations and discharges, respectively. These annual average discharge rates were obtained from the Ministry of Energy (Local Water Office).

## Groundwater use in Honam

Honam catchment is mountainous and is a karstic watershed with a small plain area and a shallow alluvial layer. Thus, this watershed has low capacity for retaining groundwater. In addition, there is little demand for groundwater. Nevertheless, there are 18 wells in the Honam Plain (Figure 3.12) and their

Figure 3.11. Diversion intakes from main irrigation channels in Honam low Lands.
characteristics are presented in Table 3.9. The water table depth is reduced from 49 to 2 m from upstream to downstream, and shows no drawdown due to overdraft of water by wells.

## B- Stream flow in Merek catchment

There are many methods to determine different parameters of monthly and annual flow measuring and estimating. There were neither discharge data available nor any hydrometric stations present in the study area at beginning of the CP project. The necessary equipment were provided and installed by the project during the first year of the study.

The CP project provided two water level meters (model Global Water 3") in Charvarish and Halashi station; however, the instrument in Halshi did not work
properly and so the Soil Conservation and Watershed Management Research Institute added a limnograph Model WBEDIEN 32 at the Halashi station in addition to the previous CP Global Water Level level Meter. Figure 3.13 and Table 3.10 show the geographic coordinates and locations of the site. A uniform and rectangular shape cross-section of Merek River below the flume allowed for measuring discharge correctly without constructing a telepheric bridge.

Annual and monthly stream flow water level was measured by limnograph and stage in two hydrometric stations. Halashi Bridge on Merek River was selected as the outlet of the whole catchment. A stage was installed and was read daily by an operator on normal days. During rainy and flood periods, the readings

were taken hourly. Figure 3.14 shows the bridge and the stage from the upstream view. The data were available in Halashi station from 21 January 2007. There was a flume across the Merek River, less than 100 m upstream of Halashi Bridge. This was the point selected for a water
level recorder (model Global Water Level Meter 9" Model) from the CP project, but it malfunctioned and was replaced by a limnograph Model WBEDIEN 32. The data of the stage were available from 21 J anuary 2007, but data from the logger were available from 21 February 2007.

Figure 3.12. Location of wells in Honam watershed.

Figure 3.15 shows the cross-section of the river with limnograph (data logger) with a stage and the flume above it.

There was a bridge at Charvarish on the main road of Merek, adjacent to Lower Tahneh village, which divided forestry sub-catchment of the southern region of Merek. In Charvarish Bridge, a water level meter (logger) was installed to measure the contribution of the forest area to total surface runoff (Figure 3.16). The data were recorded after 21 March 2007. A rating curve was drawn based on discharge-stage measurements for 24 times at different water levels. Table 3.10 shows the stage and the corresponding discharge and Figure 3.17 shows the rating curve derived for Halashi station. Data of daily and instantaneous discharge were derived using the rating curve and water level over 12 months,
to provide one year of data for water balance analysis. Table 3.11 shows the monthly discharge at Halashi station; however, stream flow was not recorded at Charvarish station due to a severe drought during the study (April 2007 to May 2008).

## Springs

There is no spring in the Merek catchment. Seepage from the river and drainage are the main type of groundwater outlet.

## Qanats

There are four qanats in Merek, situated in different parts of the plain. Qanats are monitored by the Ministry of Energy (MoE) in Iran, who carry out regular monthly monitoring of discharge and quality of the qanat in Merek. In this

study, field data was derived from the four abovementioned qanats (Figure 3.18). The mean annual flow was calculated using the mean monthly discharge data from the MoE. Table 3.12 presents the mean annual discharge from October 2006 to September 2007.

Qanat discharge was computed using Table 3.12 data. Annual discharge of the four qanats was $2.2 \times 10^{6} \mathrm{~m}^{3}$ for October

2006 to September 2007. The monthly volumes of qanat discharge are shown in Table 3.13. Qanat water resources were used for agriculture and drinking, of which about $0.25 \times 10^{6} \mathrm{~m}^{3}$ per year was allocated for village residents. Figure 3.19 shows the monthly variation of qanats in Merek plain. Peak discharge of Sarfiroozabad qanat was in May and minimum discharge in SeptemberOctober (Figure 3.19). Sarfiroozabad

was more sensitive in response to recharge than the other three qanats; the hydrograph increased more rapidly during March-May and then decreased to July, after that hydrograph shape variation gradually decreased up to October (Figure 3.19).

Wells
There are 303 wells in Merek watershed located in the mid parts of the catchment, from upper part of the plain to downstream. The wells in this area are scattered in the low lands and mostly on the banks of the river (Figure 3.20). Discharge of wells is monitored by the Ministry of Energy. Appendix I contains coordinates of the wells in Merek. Annual discharge of wells was estimated by data obtained from Water Office of

Kermanshah. Annual discharge of wells was $6.8 \times 10^{6} \mathrm{~m}^{3}$, of which $99 \%$ was used for agriculture and the other 1\% for drinking and industry (use of drinking water from wells by villages was $0.033 \times$ $10^{6} \mathrm{~m}^{3}$ ).

## Groundwater level data in Merek

In Merek, there are eight piezometer wells installed and monitored by MoE (Table 3.14). Water level of piezometer wells are measured monthly by local Water Office of Kermanshah Province. Unit hydrograph of the aquifer is an index

Figure 3.18. Geographical distribution of Merek qanats.

for the evaluation of the water level variation. The unit hydrograph of the Merek plain (Figure 3.21) was derived using observed data of water level in the piezometers during 1997-2008.

There was a decreasing trend of the water table level from the southeast to the northwest of the plain (Figure 3.22). Although some parts of the unit hydrograph were omitted due to uncertainty in the data, its overview shows seasonal variation due to dry and

Figure 3.19. Monthly discharge of qanats in Merek during October 2006 to September 2007.
wet seasons or years. Neglecting some oscillation due to error in raw data, it could be concluded that the water table of the aquifers has not undergone considerable drawdown. Seasonal variation of groundwater levels shows that the maximum water table level was in April while the minimum was in October.

## Discharge from the Merek River

Discharge from the Merek River was taken at three points: Gavani diversion dam, Gazaf diversion dam (Figure 3.23), and water taken directly from the river by pumping. Both Gavani and Gazaf diversion dams were constructed by the MoE local office, but are operated by the farmers who use the water for irrigation. These diversions convey the water by concrete-lined channels from the diversion dam to the farm land. They are used in the irrigation season (from April or May to October or November). Although the diversion dams were constructed by the government, they are monitored by the farmers - the local Water Office has no clear responsibility in operating and maintenance of the dams or the related channels.

### 3.2.3. Salas model for water balance analysis

Volume and mass equilibrium were used in hydrological water balance computations and the Salas model was used for analyzing water balance parameters. For our purposes, we used a simple water balance model that operates at the annual time-scale and requires only the precipitation data as input (Saito et al., 2008). This model assumes that the watershed is homogeneous and is composed of three storages: surface, subsurface (unsaturated zone), and groundwater (saturated zone). Each storage has input and output variables that are either known (e.g. measured or reconstructed precipitation) or calculated
by parametric relationships, and the storages are linked to each other by inputs and outputs (e.g. infiltration and deep percolation). The basic processes considered in the model are surface runoff, infiltration, evapotranspiration, deep percolation, base flow, and stream flow. Model parameters include ' $a$ ' as the fraction of precipitation that becomes surface runoff; ' $b$ ' is a fraction of infiltrated water that evaporates; ' $c$ ' is the fraction of groundwater storage that becomes base flow; and ' d ' is the fraction of groundwater storage that becomes groundwater flow. These parameters do not change with time. In addition, the model requires an initial boundary condition of starting groundwater storage.

Figure 3.22. Unit hydrograph of Merek plain

Figure 3.23. Location of diversion dams in Merek.

### 3.3. Analysis of water balance components in Honam and Merek catchments

### 3.3.1. Water balance components in Honam catchment

Data collections were carried out for one year (21 March 2007 to 20 March 2008) to estimate annual water resources and water balance components. The results are reported below.

## Precipitation

The monthly and annual precipitation in Presk rain gauge station (Table 3.15) was monitored by the Meteorological Organization of Iran from 21 March 2007 to 20 March 2008, corresponding to the first and the last day of the Iranian year
1386. The precipitation of Presk station was 826.1 mm , at an altitude of 1880 m above mean sea level. A regional mean annual precipitation equation (mentioned in the previous section) was applied for simulation of spatial distribution of this precipitation over the whole basin area. The average altitude of Honam and Presk watersheds are, respectively, 2055 and 2709 m above mean sea level and their precipitation was estimated at 735.7 and 1017.6 mm , respectively, by applying regional weighted precipitation for 21 March 2007 to 20 March 2008.

The measured monthly precipitation of Presk station (Table 3.15) was used for dividing the estimated annual basin precipitation into 'calculated' monthly precipitation (Table 3.16 and Figure $3.24)$. There was no precipitation for five months from June to the end of October.

## Stream discharge

## Zirtagh hydrometric station

The volume of outlet discharged water was $57.4 \times 10^{6} \mathrm{~m}^{3}$ in this station from 21 March 2007 to 20 March 2008; Table 3.17 and Figure 3.25 show the average
monthly discharge. The maximum discharge was in April and May and the minimum discharge in October and November. Table 3.18 shows seasonal volume and percentage of outlet discharge.

## Presk hydrometric station

Annual water yield of Presk springs (from 21 March 2007 to 20 March 2008) was $26.02 \times 10^{6} \mathrm{~m}^{3}$ (Table 3.19). Figure 3.26 shows monthly variation in discharge of Presk spring and its runoff discharge at Presk hydrometric station.

Table 3.19. Discharge in Presk hydrometric station from 21 March 2007 to 20 March 2008 corresponding to Iranian year of 1386 .

Figure 3.25. Discharge curve of Honam hydrometric station (21 March 2007 to 20 March 2008).

Honam spring and other springs in the basin
The monthly maximum, minimum, and mean discharge values of the Honam River for 1998-2005 are shown in Figure 3.27. Average annual flow was $444 \mathrm{~L} / \mathrm{s}$ and the minimum and maximum monthly discharges in October were 333 and 672 L/s, respectively. Average mean annual discharge volume was $14.0 \times 10^{6} \mathrm{~m}^{3}$. Irrigation efficiency in these lands is low and water loss is high. Despite adequate water in the middle parts of the basin, much agricultural land is under rainfed farming due to steep slopes, topographical limitations, and lack of pumping facilities to convey water from the bottom of the river to marginal uplands.

The annual volume of the spring discharge over the whole Honam watershed was about $28.02 \times 10^{6} \mathrm{~m}^{3}$. When the Presk spring runoff water measured at Presk station was added to the above figures then the total volume was $54.02 \times 10^{6} \mathrm{~m}^{3}$.

## Channel discharge for irrigation

The total mean annual use of water for irrigation was $17.0 \times 10^{6} \mathrm{~m}^{3}$ in the whole Honam plain (Table 3.8).

## Withdrawal from wells

The total mean annual use of water from wells was $1.817 \times 10^{6} \mathrm{~m}^{3}$ in Honam plain (Table 3.9).

Figure 3.26. Monthly discharge at Presk hydrometric station (2007-2008).

Figure 3.27. Monthly discharge variation of Honam spring for 1988-2005.

## Brief Honam watershed water balance

The investigation on water balance in Honam watershed for 2007-2008 is summarized below.

## a- Surface water balance at Presk station upstream

- The area of Presk sub-catchment is $67.71 \mathrm{~km}^{2}$, and precipitation was 1017.6 mm over the whole area, which means that total volume was equal to $68.9 \times 10^{6} \mathrm{~m}^{3}$.
- Discharge at Presk hydrometric station was $26 \times 10^{6} \mathrm{~m}^{3}$
These values show that excess inflow as precipitation over the whole watershed was $42.88 \times 10^{6} \mathrm{~m}^{3}$, which is more than the discharge of surface outflow. This means that sum of the evapotranspiration and probable underground outflow was $42.88 \times 10^{6} \mathrm{~m}^{3}$. There are no data on underground water flow due to karstic outcrops at the Presk hydrometric station outlet. Additionally, the annual runoff coefficient of Presk was $0.38 \times 10^{6}$.

## b- Water resources over the whole Honam watershed

The water balance of Honam watershed (Table 3.20) had the following figures for different components:

- Area was $140.49 \mathrm{~km}^{2}$
- Precipitation was 735.7 mm over the whole $140.49 \mathrm{~km}^{2}$ area, with total volume equal to $103.34 \times 10^{6} \mathrm{~m}^{3}$
- Springs
- Outlet of Presk hydrometric station (springs + runoff) was $26.0 \times 10^{6} \mathrm{~m}^{3}$
- Total discharge volume of springs was $56.8 \times 10^{6} \mathrm{~m}^{3}$, of this agriculture and drinking uses $29.75 \times 10^{6} \mathrm{~m}^{3}$ over the whole basin
- Total discharge of wells was $1.8 \times 10^{6}$ $\mathrm{m}^{3}$
- Diversion intake was $17.8 \times 10^{6} \mathrm{~m}^{3}$
- Outlet from hydrometric station was $57.4 \times 10^{6} \mathrm{~m}^{3}$

Water balance components showed that the annual runoff coefficient of Honam basin was equal to 0.56 . Usage of surface and subsurface water in Honam basin was $49.45 \times 10^{6} \mathrm{~m}^{3}$, i.e. $47.8 \%$ of total precipitation. This is a high ratio, but the
basin inflow was less than the total basin outflow by $3.35 \times 10^{6} \mathrm{~m}^{3}$, i.e. $>3.2 \%$. This shows that Honam watershed was recharged by adjacent basins through underground flow.

Outflow components from Honam basin and its precipitation were $57.4 \times 10^{6}$ and $103.34 \times 10^{6} \mathrm{~m}^{3}$, respectively, giving a surface runoff coefficient of 0.56 . This amount is 1.5 times more than the runoff coefficient at Presk in the upper part of Honam, which had a lower evapotranspiration and higher precipitation. The conclusion is that the upper part of the basin discharged high amounts of underground flow to the lower part at Presk station.

### 3.3.2. Analysis of water balance components in Merek basin

Water balance components are precipitation over the water balance area, surface and subsurface discharge (outflow), surface and subsurface recharge (inflow), and discharge by wells and qanats in the study area.

## Precipitation

Table 3.3 shows the monthly and annual precipitation in the five stations of the Meteorological Organization of Iran from April 2007 to March 2008. A rain gauge at Najafabad station was installed as complementary for recording precipitation in short intervals, but it did not have enough data for the full period and was omitted from the list of data. Correlation analysis between precipitation and elevation was used to draw several standard curves (Figure 3.28), showing relatively linear behavior of the precipitation-elevation relationship; however, the weak correlation shows that it was unlikely that precipitation was related to elevation. Sarfiroozabad data was selected as representative of midbasin precipitation for the whole basin because the site is in the middle of the

Table 3.20. Water balance components ( $10^{6}$ $\mathrm{m}^{3}$ ) at basin scale for Honam watershed.

| Source | I nflow | Outflow |
| :--- | ---: | ---: |
| Precipitation | 103.4 | $*$ |
| Surface outflow | 0 | 57.4 |

| Usage of surface flow | $*$ | 17.8 |
| Underground flow | $*$ | $*$ |
| Sum | $\mathbf{1 0 3 . 4}$ | $\mathbf{1 0 6 . 7 5}$ |

*Inflow - Outflow $=-3.35$

Figure 3.28. Precipitation-elevation relationship.
basin at an elevation near the mean basin elevation. Sarfiroozabad rain gauge mean precipitation was 412 mm from April 2007 to March 2008. Figure 3.29 shows the histogram of monthly precipitation over the Merek basin from April 2007 to March 2008. Total volume of precipitation was $125.66 \times 10^{6} \mathrm{~m}^{3}$ in the water balance period (one full year from April 2007 to the end of March 2008).

## Outlet discharge of the Merek basin

Discharge at the outlet of Merek plain was calculated based on Table 3.21. The total volume of discharge water from Merek River at Halashi station was $5.4 \times$ $10^{6} \mathrm{~m}^{3}$ from April 2007 to 20 March 2008. Table 3.21 and Figure 3.28 show average monthly discharge. The maximum discharge was in April and May and the minimum in July and August.

Figure 3.28. Monthly discharge at Merek outlet during water balance periods.

Table 3.21. Surface outlet discharge from Merek plain.

| Month | Outlet discharge $\left(\mathbf{m}^{3} / \mathbf{s}\right)$ |
| :--- | :--- |
| April | 0.58 |
| May | 0.36 |
| June | 0.03 |
| July | 0.01 |
| August | 0.02 |
| September | 0.10 |
| October | 0.12 |
| November | 0.12 |
| December | 0.19 |
| January | 0.18 |
| February | 0.18 |
| March | 0.17 |

## Discharge by wells

Discharge by wells is an important component of water balance that can be accurately recorded. The annual discharge by wells was $6.8 \times 10^{6} \mathrm{~m}^{3}$, of which $99 \%$ was used for agriculture and the other $1 \%$ for drinking and industry (drinking water from wells used by villages was $0.033 \times 10^{6} \mathrm{~m}^{3}$ ).

## Discharge by qanats

Qanat discharge was computed using Table 3.13 data. Annual discharge of the four qanats was $2.2 \times 10^{6} \mathrm{~m}^{3}$ for October 2006 to September 2007. The monthly volumes of qanat discharge are shown in Table 3.12. Qanat water resources were consumed for agriculture and drinking, of which $1.95 \times 10^{6} \mathrm{~m}^{3}$ was used for agriculture and $0.25 \times 10^{6} \mathrm{~m}^{3}$ for drinking.

## Discharge from Merek River

Water from Merek River was taken at three points: Gavani diversion dam, Gazaf diversion dam, and directly from the river by pumping. Discharge by these structures was $0.59 \times 10^{6}$ and $0.35 \times 10^{6}$ $\mathrm{m}^{3}$ per year, respectively, and abstraction by pumping was $0.005 \times 10^{6} \mathrm{~m}^{3}$ per year.

## Subsurface inflow and outflow

There were insufficient data to analyze subsurface inflow and outflow. There are limestone outcrops in the eastern part of the upstream of Merek that may discharge some groundwater through karstic channels. However, we have no information on the subsurface behavior of this karstic area.

Figure 3.29. Histogram of monthly precipitation over the Merek basin.

The Merek plain is formed from alluvium, which constitutes the structure of Merek aquifer/aquifers and recharges the wells, qanats, and seepage of the Merek River banks. Merek basin at Halashi is a part of the Merek plain and continues downstream of the Merek River to join the west part of the Mahidasht plain. It seems that there are no appreciable subsurface inflows from adjacent basins to Merek basin aquifers, but it is clear that the upper parts of Merek plain at Halashi have an elongated recharge boundary with the downstream adjacent aquifers that directly connect them. Unfortunately, there were insufficient data to analyze this recharge boundary.

### 3.4. Results of water resources and water balance estimation

The different components of water resources and the water balance of Merek were studied from April 2007 to March 2008 (Table 3.22). Annual total volume of precipitation and outlet discharge in the whole catchment were $125.66 \times 10^{6}$
and $5.4 \times 10^{6} \mathrm{~m}^{3}$, respectively. The sum of discharges by diversion intakes from the main irrigation channels was $0.945 \times$ $10^{6} \mathrm{~m}^{3}$ per year. Water use from wells and qanats was $6.8 \times 10^{6}$ and $2.2 \times 10^{6} \mathrm{~m}^{3}$, respectively.

Based on the water balance components, the surface runoff coefficient was 0.04 ; while for the whole Mahidasht watershed (including Merek and other areas up tot Doab station), with approximately 2.5 times larger area, the coefficient was 0.09 . The difference indicates that groundwater is more important than surface water in Merek catchment.

As the above results show, there was considerable difference between the sum of outflow and inflow of the water budget components in Merek at Halashi outlet. Part of the difference between inflow and outflow was due to actual evapotranspiration that could not be measured or estimated in this study; however, subsurface outflow from upper parts of Merek plain to lower parts behind Halashi section also played a role.

Table 3.22. Water balance components in a basin scale in Merek watershed.

| Type of water resource |  | Volume ( $\mathbf{1 0}^{\mathbf{6}} \mathrm{m}^{\mathbf{3}}$ ) | Type of consumption |
| :---: | :---: | :---: | :---: |
| Qanats | Sakhr | 0.39 | Agricultural use 2.21 |
|  | Sarfiroozabad | 1.44 |  |
|  | Khosravi | 0.17 |  |
|  | Ghomesh | 0.23 |  |
| Total |  | 2.24 | Domestic use 0.03 |
| Wells | 6.76 |  | Agricultural use 6.72 <br> Domestic use 0.03 <br> Industrial use 0.01 |
| Canals |  |  | Agricultural use 0.945 |
| Merek watershed outlet |  | 5.435 |  |

### 3.5. Conclusion and suggestions

The CP project team tried to install some equipment to monitor some important factors such as surface outflow and precipitation. Water balance and resource assessment were the major needs for planning natural resource use and management. Water balance or water resource components were not available for most of the basins over any time interval. Some major components were monitored by this project and some were estimated based on available data in the short period of the project. The results of research are:

1. The total outflow of the catchment showed that water was not a limiting factor for the development of this region and the supply of water was more than the demand - although there are some problems in the distribution of the available water resources over the different parts of the catchment.
2. Use of surface and subsurface water on Honam basin was $49.45 \times 10^{6} \mathrm{~m}^{3}$, i.e. $47.8 \%$ of total precipitation.
3. The basin inflow was less than the total basin outflow by $3.35 \times$ $10^{6} \mathrm{~m}^{3}$, i.e. $>3.2 \%$. The sum of
the evapotranspiration, probable underground flow, and excess outflow $\left(3.35 \times 10^{6} \mathrm{~m}^{3}\right.$ ) was the amount of water recharged by underground flow from adjacent basins.
4. The downstream outcrops of Honam did not provide enough evidence for underground outflow, therefore the underground inflow in Honam watershed was the sum of evapotranspiration plus excess outflow $\left(3.35 \times 10^{6} \mathrm{~m}^{3}\right)$. However, the data for actual basin evapotranspiration were not available to determine the amount of those two components.
5. The surface runoff coefficient over the whole Honam was 0.56 , which was 1.5 times more than the runoff coefficient at Presk in the upper part of Honam, which had a lower evapotranspiration and higher precipitation. The conclusion is that the upper part discharged a high amount of underground flow to the lower part at Presk station.
6. For future study, it is necessary to distinguish and separate the amount of underground inflow and evapotranspiration in the water balance equations, in addition to underground outflow. It is necessary to continue research for the estimation of basin evapotranspiration and recognizing geological formation
and structures in downstream sections - in which, probable underground outflow can be indirectly determined by geological setting, and evapotranspiration by a detailed water balance plus vegetation cover routing.
7. Data collection on the hydrodynamic parameters of alluvial and karstic aquifers of Honam is needed for completion of water balance analysis and determination of all water resource components.
8. Water use, precipitation, and surface water outflow and inflow were the components of water balance that were estimated reliably.
9. The results show that total water usage was $9.98 \times 10^{6} \mathrm{~m}^{3}$ and the surface water outflow $5.435 \times 10^{6}$ $\mathrm{m}^{3}$. The main use of water in Merek was for agriculture, especially for irrigation that constituted 99\% of the total water use. The remaining 1\% was used for drinking and other domestic purposes.
10. Water balance analysis shows that the runoff coefficient (0.043) was very low in Merek, which shows the importance of natural aquifer recharge and groundwater in this area.
11. One of the problems for studying water resources in this area is lack of data. Therefore, a priority for water monitoring is to continue collecting surface outflow data at Halashi Hydrometric Station. In addition, completion of the piezometric well network for observation and exploration is necessary for water management planning.

### 4.1. Introduction

For many centuries, humans have changed land use and intervened in natural resources for different purposes such as development of urban and rural residential areas or expansion of agricultural activities for food production. In some cases, these activities have resulted in deterioration and degradation of the natural resources. Such changes have affected the hydrologic regime of drainage basins dramatically and therefore land-use changes are nowadays considered a global challenge more critical than climatic change (Sala et al., 2000).

Generally, the runoff volume and hydrograph shape of flood events have been related to physical variables including soil, vegetation cover, topography, and hydrologic characteristics of the watershed. One of the manageable parameters in this regard is land use that is continuously changing. There is a relative equilibrium between physical and climatic parameters in nature, thus the formation and amount of the runoff are functions of rainfall. However, the variation of land use could result in changes in vegetation cover, infiltration rate, and roughness of the basin, all of which could affect the amount of runoff and flood hydrograph shape. Hence, variation of hydrologic regime in the long- and medium-term is a function of land use (Miller et al., 2002). The effects of such changes in hydrologic response of the basin are reflected as changes in run off depth, minimum and maximum discharge, flood volume, soil moisture, and evapotranspiration amount (Sikka et al., 2003).

Research has shown that development of urban areas would increase the peak value and runoff, while an increase in forest area would decrease these amounts (Hundecha and Bardossy, 2004).

Investigation of land-use change effect on flood event frequency indicates an increase in these phenomena (Crooks and Davies, 2001). Recently, news and reports of flood events in Iran indicate that most parts of the country are in danger of destructive and periodic floods that affect residential areas financially and socially. These phenomena have had an increasing trend during recent decades, therefore flood and flood risk is a socio-economic concern for the country, and mitigation strategies are being considered by scientists and government authorities.

The present research involves some of the factors affecting flood events and flooding area and the studies were carried out to determine hydrological behavior of the basin in response to land-use changes using the HEC-HMS model and also to develop a suitable approach for using rainfall-runoff models in other basins.

### 4.2. Literature review

Croke and Jakeman. (2001) and Fohrer, et al. (2002), in their studies on the effect of land-use changes by HECHMS, showed different results on the effect of decreasing forest area and expansion of agricultural and residential area on runoff amount. Sharifi et al. (2002) believes that the main cause of the catastrophic flood of Golestan dam basin was land-use change, especially deterioration of forests and rangeland. Sikka (2003) cites that land
use and vegetation cover management hydrologically affect the runoff, minimum and maximum discharge, soil moisture, and evapotranspiration. Similarly, Singh (1996) concluded that the runoff of a basin depended on many factors such as dynamics of rainfall, infiltration, and antecedent soil moisture. Hawkins (1997) reported that unexpected variation of curve number (CN) could change the antecedent moisture and the following runoff depth. In order to develop and improve the HEC-1 hydrologic model and GIS, Suwanwerak (1994) investigated the effect of land-use changes on past and future flood events. He also studied land-use changes of upland areas on flood pattern downstream and reported that reduction of upland forest area could increase the level of flood water downstream.

Hundecha and Bardossy (2004) used a descriptive rainfall-runoff model, to investigate the effect of land use on runoff rate and concluded that city area development could increase the peak values of flood events and, conversely, by increasing the forest area, the peak value decreased. Effect of land-use changes on flood event frequency was investigated by Croke and Jakeman (2001) in a 30year period and they concluded that the frequency was increased by land-use change. In a study of land-use change and flooding potential in a 45-year period, Khalighi (2004) used HEC-HMS and showed that by increasing area of rainfed farms from 4528 to
20231 ha, the time of concentration decreased by $14 \%$.

By combining GIS and HEC-HMS, Farazjou et al. (2007) investigated the effect of vegetation cover changes on volume and peak discharge of floods in the upland of Golestan dam basin. They predicted the hydrologic response of the basin in different land-use scenarios, and their results showed that the vegetation
cover effects were limited in capacity to control catastrophic flooding with high frequency. Moreover, they showed that in a pessimistic scenario of land-use change with deteriorating trends in forest and rangeland and expansion of farming area the values of flood peak with a return period of 5-100 years would be increased by $24-35 \%$.

Using outlet hydrograph analysis by assuming lumped basin, Khosroushahi and Saghafian (2005) investigated some factors affecting flooding, such as land use, vegetation cover, and climatic factors in the sub-basins. They concluded that hydrologic responses of sub-basins in relation to outlet discharge were nonlinear processes. They showed that the CN was the most important factor in flood mitigation strategies.

By using HEC-HMS and GIS for flood simulation in reservoir routing, Farajzadeh (2004) concluded that the HEC-HMS models were suitable for simulation of flood events. Also, in simulation of rainfall-runoff using the HEC-1 model, Morid et al. (1998) concluded that this model could give reasonable results; however, hydrographs with a normal bell shape should be used in its calibration. Jahantigh (2000) demonstrated that HEC-HMS was a suitable model for Sivand River in Kor basin of Fars Province and concluded that hydrologic-based models had greater capability to predict runoff compared to hydraulic-based models. Shaghaghi (2002) used the HEC-HMS model for simulation of peak discharge in tributaries of Mohammadabad Basin in Golestan Province, and estimated runoff using rainfall data and found reasonable agreement between the results and the observed values.

### 4.3. Materials and methods

### 4.3.1. Procedure

In this study, in order to investigate effects of land-use changes, the following actions were carried out:

- Collecting and estimating physiographic data and the required parameters
- Collection of rainfall and flood events data in Honam basin, and computed or estimated the required parameters
- Preparation of land use map
- Preparation of hydrologic soil groups data in the basin
- Overlaying land use map and hydrologic soil group data for estimation of basin CN, using weighted mean methods
- Input of information into the HECHMS software in order to simulate rainfall-runoff in the basin
- Setup of primary rainfall-runoff model
- Calibration of the parameters
- Validation of the calibrated parameters
- Using CN in the optimistic and pessimistic scenarios
- Comparison of model output of simulated hydrograph, analysis of the results, and conclusion
- Suggesting improved land-use management for the future

### 4.3.2. Study area

## Geographic location

Honam is a catchment as a part of Sarab-Sayed Ali sub-basin in the upper northeast part of the KRB in southwest Iran (Figure 4.1a). It is located within $49^{\circ} 08^{\prime}-49^{\circ} 17^{\prime} \mathrm{E}$ and $33^{\circ} 30^{\prime} 15^{\prime \prime}$ $33^{\circ} 37^{\prime} 11$ " N . This catchment has an area of $140 \mathrm{~km}^{2}$ and an elevation range of 1480-3560 m above mean sea level.

Figure 4.1a Honam basin and drainage network in the upper KRB.

Figure 4.1b. Merek catchment and drainage network in upper Karkheh.

Merek catchment is a part of Polchehr sub-basin in the upper northwest of the KRB in southwest Iran (Figure 4.1b). It is located within $47^{\circ} 04^{\prime} 30^{\prime \prime}-47^{\circ} 22^{\prime} 30^{\prime \prime}$ E and $34^{\circ} 01^{\prime}-34^{\circ} 09^{\prime} 30^{\prime \prime} \mathrm{N}$. This catchment has an area of $309.1 \mathrm{~km}^{2}$ and an elevation range of 1440-2760 m above mean sea level.

## Land use

The land use map was produced in Arc GIS using Landsat TM images of 2002 (Mirghasemi, 2008). Figure 4.2 shows the different land uses and percent of variation of each unit in the Honam basin. Figure 4.3 is a view of land use in Honam
(April 2005). The mountainous areas are rangelands and lower parts are cultivated areas.

Figure 4.4 shows the different land uses and percent of variation of each unit in Merek in Halashi basin. The mountainous areas are rangelands and the lower parts are cultivated.

## Soil texture

The soil texture of the Honam catchment is mainly clay to silt in the plains area with medium permeability due to the presence of high amounts of fine gravel. A large percentage of the hills and hillside

Figure 4.2. Land use map of Honam catchment in 2002.

Figure 4.3. A view of land use in Honam (April 2005).
areas are covered by (mostly fine) rocks. Hydrologic soil groups map was produced according to soil texture (Milani, 2009) and infiltration rates in different parts of the basin. Figure 4.5 shows
the soil texture and Figure 4.6 shows the corresponding infiltration index or hydrologic soil groups, where No. 3 and 4 correspond to hydrologic soil groups $C$ and $D$, respectively.

The soil texture of the Merek catchment is mainly clay-silt in the plains area and has medium permeability due to high amounts of fine gravel. In the hill and hillside areas, the percentage of rock and fine rock is high. A soil hydrologic group map (Figure 4.8) was produced from soil texture (Figure 4.7) according to Milani (2009).

The area of hydrologic soil groups and corresponding CNs in Merek catchment (Table 4.1) were prepared by crossing Figure 4.4 and Figure 4.8. The weighted average of CN was 76.53 , with a

Figure 4.4. Land use map of Merek catchment in 2002.

Figure 4.8. Hydrologic group map of Merak basin.
minimum of 55 for an area of 8.844 $\mathrm{km}^{2}$ of moderately forested parts, and maximum CN of 100 for the $6.814 \mathrm{~km}^{2}$ covered by rock outcrops (Table 4.1).

### 4.4. Approach of HEC-HMS model

The HEC series software was prepared by the Hydrologic Engineering Center of the US Army in different hydrologic, hydraulic, and water engineering sections and has been internationally recognized. The first series of this software is HEC1 , which is specific to hydrology, and was developed in 1968 and is capable of simulating response of the watershed in a rainfall event as a flood or surface runoff.

In the 1990s, a Windows operating system of the new and graphical version of the software was developed as HEC-

HMS, by the above Center. This program is essentially modern software with a Windows interface and some features that make it more user friendly for simulation of rainfall-runoff in basins, water supply studies, flood hydrology, predicting basin response to urban developments, surface water drainage, reservoir spillway designing, flood mitigation, and management of flood plain areas.

### 4.4.1. Modeling processes and estimation

Simulation of hydrologic processes by HEC-HMS includes three main components: basin model, meteorological model, and control specifications. Watershed model includes estimation of watershed losses, transformation of rainfall to runoff, amount of base flow and simulation channels and reservoirs routing in basin model. One basic component of the basin model is basin

Table 4.1. Area of hydrologic soil groups and corresponding CN in Merek basin.

| Land use | Hydrologic soil groups | CN | Area <br> ( $\mathrm{km}^{2}$ ) |
| :---: | :---: | :---: | :---: |
| Bare land | D | 86 | 0.16 |
|  | B | 76 | 139.60 |
| Dry farming | C | 84 | 14.29 |
|  | D | 88 | 4.34 |
|  | B | 66 | 8.75 |
| Low dense forest | C | 77 | 0.75 |
|  | D | 83 | 12.58 |
|  | B | 55 | 8.85 |
| Moderate dense forest | C | 70 | 1.83 |
|  | D | 77 | 9.51 |
|  | B | 60 | 0.30 |
| Orchards and arboriculture | C | 73 | 0.08 |
|  | B | 69 | 21.90 |
| Irrigated farming | C | 78 | 2.90 |
|  | D | 83 | 2.55 |
|  | B | 67 | 3.40 |
| Rangeland and dry farming | C | 81 | 0.29 |
|  | D | 88 | 7.51 |
|  | B | 79 | 35.60 |
| Moderate rangeland | D | 89 | 2.80 |
|  | B | 69 | 7.40 |
| Poor rangeland | C | 86 | 0.59 |
|  | D | 84 | 5.60 |
|  | B | 61 | 5.40 |
| Good rangeland | C | 74 | 1.31 |
|  | D | 80 | 2.88 |
| Rock | B | 100 | 6.85 |
|  | B | 92 | 0.94 |
| Urban | C | 95 | 0.07 |
|  | D | 95 | 0.06 |
| Weighted average of CN$=76.5$ |  | Sum of area $=309 \mathbf{~ k m}^{2}$ |  |

area, which in Honam basin was set to $140.16 \mathrm{~km}^{2}$. Selection of methods for calculation of the losses and estimation of its required parameters is an important
step in the basin model. There are different methods for calculation of losses based on the user's choices, including the following:

- Flow deficiency and constant-rate losses model
- SCS model (simple and girded)
- Green and Ampt model
- Soil moisture accounting model
- Initial and constant rate model

The SCS simple model was selected for the present research, due to the available information and data layers. Simplicity of the model and the minimum data requirement are the reasons that SCS has been applied worldwide and in many projects over the last 50 years.

Calculation of losses in this method needs the determination of CN , initial losses, and percentage of impervious area. The famous CN model introduced by SCS considers excess rainfall as a function of cumulative rainfall, vegetation cover, land use, and antecedent soil moisture. By analyzing some small experimental watersheds, the SCS developed an empirical equation between initial abstraction (Ia) and specific retention (S), as Ia $=0.2 \mathrm{~S}$, and suggested that this amount could be changed to as much as 0.05 S by local calibration.

Maximum interception could be correlated to catchments characteristics and CNs. The CN values in a basin are a function of land use, soil type, and antecedent soil moisture. Generally, the CN value varies from 100 for impervious surfaces to 30 for highly permeable soil. By applying these factors, the estimated CN was 79.1, as a weighted average for the study area. Thus, S was 67.1 mm and the initial loss ( $\mathrm{I} \mathrm{a}=0.2 \mathrm{~S}$ ) was 13.4 mm .

To investigate the land-use change effects in management and programming processes in the study area, two
conditions of optimistic and pessimistic scenarios were considered, based on the latest conditions of land use. The pessimistic scenario implies the deterioration of vegetation cover and land disturbance and with increasing trends, while in the optimistic scenario the land use is assumed under suitable management condition. The condition for such a scenario is that $S=67.12 \mathrm{~mm}$ and $\mathrm{I} \mathrm{a}=13.43 \mathrm{~mm}$.

Based on the residential areas, rock outcrops, and hard surface roads, the impervious area was estimated as 2\% and was inputted into the model.

For runoff estimation and the required parameters, there are different methods to calculate runoff from sub-basins, but users can only select one of the following:

- Modified Clark method
- Snyder method
- Kinematics wave method
- SCS method
- User-specified S Graph method
- User-specified unit hydrograph method

The SCS method was used in the present research, due to available information and data, in which lag time is the main input parameter for the model.

The following equation was used to calculate lag time ( $\mathrm{t}_{\text {lag }}$ ) in SCS methods:
$\mathrm{T}_{\text {lag }}=\left(\left(10.8 *(\mathrm{~s}+1)^{0.7}\right) /\left(1900^{*} \mathrm{y}^{5}\right)\right.$
Where, $\mathrm{t}_{\text {lag }}$ is the lag time of the basin $(\mathrm{h}), \mathrm{I}$ is main channel length (feet), y is mean slope (\%), and $s$ is the index of water retention in the basin (inches).

Table 4.2. Constant monthly discharge in Honam catchment.

| Month | Feb | March | December |
| :--- | :--- | :--- | :--- |
| Constant discharge <br> $\left(\mathrm{m}^{3} / \mathrm{s}\right)$ | 1.7 | 4.42 | 2 |

Table 4.3. Constant monthly discharge in Merek catchment.

| Month | March | April | May |
| :--- | :--- | :--- | :--- |
| Constant discharge <br> $\left(\mathrm{m}^{3} / \mathrm{s}\right)$ | 0.5 | 0.48 | 0.43 |

Using this equation and the CN of the study area, the lag time was estimated at 14.22 h . The value of s was calculated by the following equation;
$\mathrm{s}=(100 / \mathrm{CN})-10$
I was estimated using topography and drainage system, and y was calculated using the slope map.

### 4.4.2. Base flow calculation

In each sub-basin, base flow can be calculated using the following methods:

- Recession method
- Constant monthly method
- Linear reservoir method
- Bounded recession method

In the present research, according to the available data and information, the constant monthly method was used to calculate the base flow, hence, it was necessary to obtain the constant monthly discharge. Using the data of 2008 as a baseline, constant monthly discharges for 2008 were calculated for Honam and Merek catchments (Tables 4.2 and 4.3, respectively).

### 4.4.3. Meteorological model

The meteorological model includes rainfall and evapotranspiration components. In order to analyze rainfall data, the following methods can be used:

- User specified hyetograph
- SCS hypothetical storm
- Frequency storm
- Girded precipitation
- Gauge weighting inverse distance
- User specified weighting

In this research, according to the available data, the user specified hyetograph method was used and the hyetograph of rainfall events was input for the model. In this research two storm events were used for model calibration and validation. It is to be noted that there was only one rain gauge recorder in the Honam catchment and that was used for the study of temporal pattern of the rainfall. The mean rainfall value over the basin was calculated by using daily precipitation of this station by the weighting mean method.

### 4.4.4. Control specifications

Control specifications are the other components for hydrologic simulation by HEC-HMS. The date and time of start of a project was introduced in this step. The final task in the model setup involves establishing the model's time limits.

### 4.4.5. Data analysis for rainfallrunoff relationship and optimizing the model's parameters

Calibration and data analysis for rainfallrunoff relationships are another step in the HEC-HMS model. In the modeling processes, the result of the first run of the model can be calibrated and optimized in three conditions:

1. Automatic method, in which the model itself optimizes the parameters
2. Manual method
3. Both manually and automatically

HEC runs automatically for optimizing parameters, but the user can manually manage it by putting the first estimation as input data for the model. The model automatically carries out optimization by minimizing the difference between the observed and the estimated hydrograph to attain reasonable results. The objective function was Percent Error Peak, and the optimization method was Univariate

Gradient, which were put in the model structure.

### 4.5. Processing Honam catchment data

### 4.5.1. Data collection and model setup

The Aleshtar hydrometric station is located at the outlet of the basin. Data of flood discharge and the corresponding storm event were extracted from records of this station. A hydrograph of each storm event was extracted by considering the date of the storm and was then used in the HEC-HMS model.

Figure 4.9 and 4.10 show the hydrographs of 7 December 2007 and 26 February 2008 at the outlet of Honam (at Aleshtar station), respectively.

### 4.5.2. Model setup, calibration, and validation

In order to use HEC-HMS and prepare a rainfall-runoff model to study the effects of land-use change on runoff, the required information and data layers were prepared, and then setup as input for the model. The parameter calibration was carried out with one event and the model accuracy was validated with another event in the next step.

### 4.5.3. Rainfall- runoff simulation by the model

To calibrate the model, the parameters were estimated based on available data, which were used as the first trial for the input of the model. These parameters included CN as 79.1, initial loss of 13.43 mm , and the lag time of 853.2 min and were used as input of the model to simulate the flood hydrograph, e.g. the simulated and observed hydrographs based on the storm of 25 February 2008 (Figure 4.11). Comparison of the

Figure 4.9. Hydrograph of storm event on 7 December 2007.

Figure 4.10. Hydrograph of storm event on 26 February 2008.
two hydrographs indicates considerable difference in peak values and other dimensions; therefore, another trial to calibrate the required parameters is necessary.

Model calibration and parameter optimization were continued in the next step, which used the first step parameters as the initial input and continued automatically to optimize the parameters. Calibration is a process in which the initial parameters are corrected
by comparison with the results of the model. It is possible to calibrate the model automatically and manually.

Calibration of the model was carried out, based on objective function of percent of error in peak discharge since the purpose of this study was to investigate peak discharge variations.

Since the estimated and the observed peak discharge and storm volume differed, attempts were made to change

Figure 4.11. Observed and simulated hydrograph of the storm on 25 February 2008.

Figure 4.12. Calibrated and observed hydrographs of the storm of 25 February 2008.
the parameter so that those values were close to the real values. The lag time and initial loss also changed. The initial loss value changed from 13.43 to 17.43 mm (i.e. coefficient 0.2 S increased to
0.26 S ) and the lag time decreased from 853 to 410.7 min . Finally, the calibrated parameters obtained were as follows: lag time equal to 410.7 min, initial loss 17.43 mm or 0.26 S , and CN equal to 79.1.

Table 4.4. Parameters including CN, initial loss, lag time, peak discharge, and flood volume in calibration steps based on the storm of 25 February 2008.

| Date | I nitial loss (mm) | Lag time (min) | Peak discharge ( $\mathrm{m}^{3} / \mathrm{s}$ ) | Storm volume ( $\mathbf{M m}^{\mathbf{3}}$ ) | Hydrograph description |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 25Feb 2008 | 13.43 | 853.2 | 3.1 | 2.91 | Observed |
|  |  |  | 3.9 | 3.28 | Estimated |
|  | 17.43 | 410.7 | 3.1 | 3.1 | Calibrated |

Figure 4.12 shows the simulated and the observed hydrographs based on the storm of 25 February 2008, in the calibration step. The result of calibration is summarized in Table 4.4, which shows the values of CN, initial loss, lag time, peak discharge, and flood volume.

### 4.5.4. Model validation

Validation is the process for evaluation of calibrated parameters, therefore the accuracy of the corrected parameters was evaluated in this step. To this end, the corrected parameters of the model were applied to the new rainfall event

Table 4.5. The observed and optimized hydrograph parameters in model validation.

| Date | Peak discharge $\left(\mathbf{m}^{\mathbf{3} / \mathbf{s})}\right.$ |  |  | $\begin{array}{l}\text { Flood } \\ \text { volume } \\ \left(\mathbf{M m}^{\mathbf{3}}\right)\end{array}$ | $\begin{array}{l}\text { Total } \\ \text { rainfall } \\ (\mathbf{m m})\end{array}$ | $\begin{array}{l}\text { Total } \\ \text { rainfall loss } \\ (\mathbf{m m})\end{array}$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | \(\left.\begin{array}{l}Total direct <br>

runoff <br>
\left(\mathbf{M m}^{\mathbf{3}}\right)\end{array}\right]\).

Figure 4.13. The observed and simulated hydrographs in validation steps for the storm of 6 December 2007.
to determine whether the observed and simulated hydrographs were similar. The storm of 6 December 2007 was selected for validation. The observed and estimated hydrograph parameters in validation step are presented in Table 4.5, which shows that the error percent for peak discharge and hydrograph volume were in acceptable range; thus, the model could be validated. Figure 4.13 depicts the observed and simulated hydrographs in validation steps for the abovementioned storm.

### 4.6. Scenarios of hydrologic response to land-use change

The main goal of this study is simulation of the effects of land-use changes on
runoff magnitude in the watershed. Therefore, for different land-use conditions, the pertinent hydrographs were simulated.

Scenarios of land-use change are of two types: optimistic and pessimistic. Hence, these two scenarios were assumed for Honam basin land-use in the future. In the optimistic condition, due to improved vegetation cover and suitability of Iand use, the CN decreased and reached a value of 68 . In the pessimistic condition, however, trends of the last three decades continued and CN increased to 85.

The optimistic condition implies proper management practices, while the pessimistic condition assumes increasing trend of disturbance over the catchments.

Table 4.6. Peak value, flood volume, total rainfall loss, and direct runoff in pessimistic condition.

| Peak discharge <br> $\left(\mathbf{m}^{\mathbf{3} / \mathbf{s})}\right.$ | Flood volume <br> $\left(\mathbf{M m}^{\mathbf{3}}\right)$ | Total rainfall <br> $\left(\mathbf{M m}^{\mathbf{3}}\right)$ | Total loss <br> $\left(\mathbf{M m}^{\mathbf{3}}\right)$ | Total direct runoff <br> $\left(\mathbf{M m}^{\mathbf{3})}\right.$ |

| 3 | 3.83 | 27.65 | 27.1 | 0.55 |

Figure 4.15. Simulated hydrograph for optimistic scenario.

With the other conditions kept constant and assuming a constant lag time of 410.7 min for both scenarios, Figure 4.14 and 4.15 show the simulated hydrographs of the optimistic and pessimistic conditions, respectively; and Tables 4.6 and 4.7 show the corresponding peak value, flood volume, base flow, total rainfall and total direct runoff.

### 4.7. Processing Merek catchment data

### 4.7.1. Data collection and model setup

## Flood data

Obviously, data of the temporal and spatial pattern of precipitation are essential for rainfall-runoff analysis; however, when the study began there was no rain gauge recorder in the

Merek catchment. Therefore, a weighing recorder rain gauge was installed in the middle of the catchment (Najafabad village) on May 2007. In addition, four standard rain gauges were available for rainfall spatial analysis, two of which were situated in the study area and the others in adjacent basins (Figure 4.16 and Table 4.8).

## Discharge of floods

At the beginning of this research project, there were no hydrometric stations and no discharge data for the study area. Therefore, the necessary equipment were provided by the project and installed during the first year of the study. Two water level recorders (model Global Water Level Meters (3 inch) were installed in Charvarish and Halashi sections. However, the one in Halashi did not work properly and, therefore, the Soil Conservation and Watershed Management

Figure 4.16. Geographical coordinates and locations of the rain gauge stations.

Table 4.8. Type and coordinates of the rain gauges used in this study.

| Name of location | Types | Longitude | Latitude | Elevation (m) | Time interval of <br> measurements |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Boojan | Standard rain gauge | $47^{\circ} 15^{\prime} 00^{\prime \prime}$ | $33^{\circ} 58^{\prime} 00^{\prime \prime}$ | 1600 | 12 h |

storm event were extracted from records of this station. A hydrograph of each storm event was extracted by considering the date of the storm and was then used in HEC-HMS model. Figure 4.19 and Figure 4.20 show the hydrographs of 11 April and 25 March 2007, in the outlet of Merek (at Halashi station), respectively.

Figure 4.19. Hydrograph of the storm event on 25/03/2007.

### 4.8. Model setup, calibration, and validation

In order to use HEC-HMS and prepare a rainfall-runoff model for investigation of land-use change effects on runoff, the required information and data layers were prepared and setup as input of the model. The parameter calibration was carried out with one event and afterwards the model accuracy was validated with another event.

### 4.8.1. Rainfall- runoff simulation by model

To calibrate the model, the parameters were estimated based on the available data, which were used as the first trial for the input of the model. The parameters included $\mathrm{CN}=76.5$, the antecedent soil moisture, with the moisture condition based on the previous 5 d of rainfall set in group II (moist group based on SCS), initial loss of 14.3 mm , and lag time of 283 min . These parameters were used as

Figure 4.20. Observed and simulated hydrograph of the storm of 25 March 2007. 2007.
inputs of the model and a hydrograph of the flood was simulated.
Figure 4.20 shows the simulated and the observed hydrograph based on the storm of 25 March 2007. Comparison of the observed and simulated hydrograph indicates considerable difference in the peak values and other dimensions and make another trial necessary to calibrate the required parameters.

Model calibration and parameter optimization was continued in the next step, which used the first step parameters as initial input and automatically optimized the parameters. Calibration is a process in which the initial parameters are corrected by comparison with the results of model. It is possible to calibrate the model automatically and manually.

Calibration of the model was carried out based on the objective function of percent of error in peak discharge, since the purpose of this study was investigation of the peak discharge variations.

Since the estimated and observed peak discharge and storm volume differed, attempts were made to change the parameter so that those values were close to the real values. The lag time and initial lose also changed. The initial loss value changed from 14.33 to 38.8 mm (i.e. coefficient 0.2 S increased to 0.54 S) and the lag time decreased from 280 to 606 min . Finally the calibrated parameters obtained were as follows: lag time equal to 606 min , initial loss 38.8 mm (or 0.5 S ), and CN equal to 78.6.
Figure 4.21 shows the corresponding

Figure 4.21. Calibrated and observed hydrographs of storm of 25 March 2007.

Table 4.10. Parameters including CN, initial loss, lag time, peak discharge, and flood volume in calibration steps based on the storm of 25 March 2007.

calibrated and observed hydrographs for this event. The results of calibration are summarized in Table 4.10, which shows the values of CN, initial loss, lag time, peak discharge, and flood volume.

### 4.8.2. Model validation

Validation is the process for evaluation of the calibrated parameters; therefore accuracy of the corrected parameters was evaluated in this step. To this end, the corrected parameters of the model were applied to the new event to determine whether the observed and the simulated hydrographs were similar. The storm of 11 April 2007 was selected for validation. The observed and estimated hydrograph parameters in validation step are given in Table 4.11, which shows that the error percent for peak discharge and the hydrograph volume
are in acceptable range. Thus, the model could be validated. Figure 4.22 shows the observed and the simulated hydrographs in validation steps for the storm of 11 April 2007. Since the error percent for peak discharge and hydrograph volume are in acceptable range ( $0.5 \%$ and $5.76 \%$ respectively) the model could be considered as validated.

### 4.9. Scenarios of hydrologic response to land-use change

The main goal of this part of the study was to simulate the effects of land-use changes on runoff magnitude in the Merek watershed. For this purpose, the pertinent hydrographs were simulated for different land use conditions.

Two scenarios of land-use change were considered for the study: optimistic and pessimistic. In the optimistic condition, the CN decreased to 60 due to improving vegetation cover and suitable land; while in the pessimistic condition, CN value reached 86 , as a consequence of continuing management trend of the last three decades.

The optimistic condition implies proper management practices and the
pessimistic condition considers increasing land-use disturbance over the catchment. The other conditions are assumed constant in the storm dated 11 April 2007 with rainfall amount of 59.7 mm .

In the optimistic scenario, the lag time value was kept constant ( 606 min ), but the effects of land-use changes decreased CN to 68 and accordingly increased the initial losses to 0.54 S .

Figure 4.23. Simulated hydrograph for the pessimistic scenario.

Figure 4.24. Simulated hydrograph for the optimistic scenario.

Table 4.12. Peak value, flood volume, total rainfall loss, and direct runoff in the pessimistic scenario.

| Peak charge <br> $\mathbf{( \mathbf { m } ^ { \mathbf { 3 } } \mathbf { s } )}$ | Flood volume $\left.\mathbf{( M m}^{\mathbf{3}}\right)$ | Total rainfall $\left.\mathbf{( M m}^{\mathbf{3}}\right)$ | Total loss <br> $\left(\mathbf{M m}^{\mathbf{3}}\right)$ | Total direct runoff <br> $\left(\mathbf{M m}^{\mathbf{3}}\right)$ |
| :--- | :--- | :--- | :--- | :--- |
| 4.6 | 0.886 | 59.7 | 40.97 | 0.583 |

Table 4.13. Peak discharge, flood volume, total rainfall loss, and direct runoff in simulated hydrograph in the optimistic scenario.

| Peak charge <br> $\left(\mathbf{m}^{\mathbf{3} / \mathbf{s})}\right.$ | Flood volume $\left.\mathbf{( M m}^{\mathbf{3}}\right)$ | Total rainfall $\left.\mathbf{( M m}^{\mathbf{3}}\right)$ | Total loss <br> $\left(\mathbf{M m}^{\mathbf{3}} \mathbf{)}\right.$ | Total direct runoff <br> $\left(\mathbf{M m}^{\mathbf{3}}\right)$ |
| :--- | :--- | :--- | :--- | :--- |
| 0.7 | 0.347 | 59.7 | 58.33 | 0.045 |

In the pessimistic assumption, the lag time value was kept constant ( 606 min ) as for the optimistic scenario; however, the effects of land-use changes increased CN to 86 and accordingly decreased the initial losses to 0.2 S .

Figure 4.23 and Figure 4.24 depict the simulated hydrographs of the optimistic and pessimistic scenarios; and Tables 4.12 and 4.13 show the corresponding peak values, flood volumes, base flows, total rainfalls, and total direct runoff.

### 4.10. Discussion and conclusion

### 4.10.1. Model calibration

## In Honam

In the first step of calibration, there was considerable difference between the observed and simulated hydrographs. In that step, the hydrograph of the storm of 26 February 2008 had a peak value and flood magnitude of $3.1 \mathrm{~m}^{3} / \mathrm{s}$ and $2.91 \mathrm{Mm}^{3}$, respectively; whereas, in the simulated hydrograph, the corresponding values were $3.9 \mathrm{~m}^{3} / \mathrm{s}$ and $3.28 \mathrm{Mm}^{2}$ with errors of $12.7 \%$ in the peak value and $25.8 \%$ in runoff volume. However, after the second step in calibration, the new values estimated for the peak discharge
and storm volume were $3.1 \mathrm{~m}^{3} / \mathrm{s}$ and 3.1 $\mathrm{Mm}^{3}$, respectively, which were close to the observed values. In this study, lag time changed from 853.2 to 410.7 min.

## In Merek

Generally speaking, model calibration requires a large amount of data; especially, storm events having considerable runoff should be available in different conditions to present the complexity and variety of the nature of the basin. A severe drought occurred during the monitoring step of the project, and so there were only two storm events data available for the study area. Therefore, one event was allocated for calibration and the other for evaluation and validation of the model parameters. This amount of data is the minimum for modeling of the basin. By using this minimum event data, we had to limit the trial and error iterations for calibration. Therefore, the physical hydrologic parameters such as CN, lag time, and initial abstraction/loss obtained from physiographic study by experimental methods were used as the first trial. In the primary step of the calibration there was considerable difference between the observed and the simulated hydrographs, e.g. in the hydrograph of 25 March 2007, the peak value and flood magnitude were $1.94 \mathrm{~m}^{3} / \mathrm{s}$ and 0.445
$\times 10^{6} \mathrm{~m}^{3}$, respectively, whereas in the simulated hydrograph the corresponding values were $4.2 \mathrm{~m}^{3} / \mathrm{s}$ and $0.886 \times 10^{6}$ $\mathrm{m}^{3}$ with error of $46.19 \%$ in peak value and $50.23 \%$ in runoff volume. After the second step in calibration by trial and error, the new values of estimation for peak discharge and storm volume were 1.9 and $0.488 \times 10^{6} \mathrm{~m}^{3}$, respectively, that were close to the observed values. In this study lag time changed from 280 to 6006 min.

### 4.10.2. Change of land use

## In Honam

The hydrologic response of Honam basin by HEC-HMS shows that land-use change is one of the most important components of hydrologic factors affecting contribution of rainfall to runoff. Optimistic and pessimistic scenarios indicate that unsuitable use of land would increase flood volume and peak discharge, whereas improving land-use condition would decrease peak value and volume of flood under the same condition or in a unique rainfall event.

## I n Merek

Since land-use change affects the vegetation cover, land management and other factors affecting surface physical properties of soil and ground directly change the infiltration response. Such a change may be a long-term process, and there are usually no historic data on landuse change. The available data on landuse change were usually restricted to one or two time steps, therefore the historic data of land use and corresponding floods did not exist to evaluate the actual response of the basin to such changes. Thus, existing land use was selected as a base and future trends were predicted according to two scenarios. Hydrologic response of Merek basin simulation by HEC-HMS shows that land-use changes as an important component of hydrologic factors affecting contribution of rainfall
to runoff. Optimistic and pessimistic scenarios indicate that unsuitable use of land would increase flood volume and peak discharge, whereas improving landuse condition would decrease peak value and volume of flood in the same storm event conditions.

The CN method is one method used to simulate loss or excess rain from a storm. As the method can be applied to basins with minimum recorded data, it has been widely used in hydrologic applications. CN as a hydrologic parameter used in rainfall-runoff simulations is itself a function of land-use changes. In this research, the value of CN was estimated at 79.1 and 76.5 for Honam and Merek, respectively, based on the physical conditions of the two basins under semiwet conditions. In the optimistic and pessimistic scenarios, CN was estimated at 60 and 86 , respectively. Since the CN reflects the land-use effect on runoff and rainfall loss, the more the increase in CN , the more will be the decrease in retention potential and the increase in runoff amount over the basin surface.

### 4.10.3. Peak discharge and flood volume

## In Honam

The simulation results of the calibrated models in Honam basin gave the peak value and flood volume of the $27-\mathrm{mm}$ rainfall event of 6 December 2007 as 4.8 $\mathrm{m}^{3} / \mathrm{s}$ and $3.86 \mathrm{Mm}^{3}$, respectively. These values decreased to $3 \mathrm{~m}^{3} / \mathrm{s}$ and $3.83 \mathrm{Mm}^{3}$ in the optimistic scenario, respectively, (Table 4.7) and increased to $11.3 \mathrm{~m}^{3} / \mathrm{s}$ and $7.83 \mathrm{Mm}^{3}$ in the pessimistic scenario (Table 4.6).

## In Merek

The results of the simulated and calibrated models in Merek catchment gave the peak value and flood volume of the rainfall event of 25 March 2007 as 1.9 $\mathrm{m}^{3} / \mathrm{s}$ and $0.488 \times 10^{6} \mathrm{~m}^{3}$, respectively

Figure 4.25. Simulated hydrographs of current land use, and optimistic and pessimistic scenarios.
(Yousefipanah, 2007). These values decreased to $0.7 \mathrm{~m}^{3} / \mathrm{s}$ and $0.347 \times 10^{6}$ $\mathrm{m}^{3}$ in the optimistic scenario, respectively, and increased to $4.6 \mathrm{~m}^{3} / \mathrm{s}$ and $0.886 \times$ $10^{6} \mathrm{~m}^{3}$ in the pessimistic scenario.

### 4.10.4. Hydrograph shape

## In Honam

Figure 4.25 and Table 4.14 show the simulated hydrographs of the basin in the two scenarios for the 6 December 2007 rainfall. Investigation of the simulated hydrograph of HEC-HMS shows that the overall shapes of the pessimistic and the observed 6 December 2007 hydrographs are similar to each other, reflecting the lumping response of the basin (using weighted mean parameters). However, the rising and falling limbs are sharper in the pessimistic than in the optimistic
condition. Moreover, the optimistic hydrograph is clearly flatter and differs to the other two.

## In Merek

Figure 4.26 shows the simulated hydrographs of the basin in the two scenarios of optimistic and pessimistic conditions for 25 May 2007. Investigation of the simulated hydrograph by HECHMS showed that the overall shapes of the pessimistic and the 25 May 2007 observed hydrographs were not similar. The pessimistic condition had a sharp rising and falling limb, but hydrograph of the optimistic condition has a very flat shape. The peak discharge in the pessimistic condition is more than six times larger than the optimistic condition and twice that of the observed one. Some similarity in the hydrographs may be due

Table 4.14. Values of peak discharge, flood volume, total rainfall loss, and direct runoff in observed and in simulated hydrographs in pessimistic and optimistic scenarios.

| Condition | Peak discharge <br> $\left(\mathbf{m}^{\mathbf{3} / \mathbf{s})}\right.$ | Flood volume <br> $\left(\mathbf{M m}^{\mathbf{3})}\right.$ | Total rainfall <br> $\left(\mathbf{M m}^{\mathbf{3})}\right.$ | Total loss <br> $\left(\mathbf{M m}^{\mathbf{3})}\right.$ | Total direct runoff <br> $\left(\mathbf{M m}^{\mathbf{3})}\right.$ |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Observed | 4.8 | 3.86 | 27.65 | 25.77 | 1.81 |
| Pessimistic | 13 | 7.83 | 27.65 | 22.29 | 5.22 |
| Optimistic | 3 | 8.5 | 27.65 | 27.1 | 0.55 |

Figure 4.26. Simulated hydrographs of existing land use, and optimistic and pessimistic scenarios.
to a reflection of accounting the whole catchment as one hydrologic unit and, therefore, this is a lumping response of the basin (using weighted mean parameters).

### 4.11. Conclusion and suggestions

The results of this study on the effects of land-use changes on runoff and hydrograph shapes using HEC-HMS in Honam and Merek basins indicated the following points:

- The result emphasize the effects of land-use changes in hydrologic response of the basin. The simulation by HEC-HMS in the studied periods shows that, by continuing unsuitable land-use trends, the peak values and flood volume would increase, whereas proper land use would decrease them. In addition to peak values and flood volume, the shapes of hydrograph would be affected, i.e. the rising and falling limbs of hydrographs of pessimistic scenarios would be much sharper and steeper relative to the optimistic scenario.
- The main effect of the land-use changes on runoff amount was the change in potential of retention of a basin that is a function of vegetation cover type and density.
- Use of this model in different surface runoff studies would save the expenses of field studies.

Considering the findings of this research, the following are suggested:

- The changing of land use to a condition with intense vegetation cover will considerably decrease the peak runoff and volume of floods over the catchments. Therefore, the first suggestion is to change the present land use in Honam and Merek basins and adopt a management method to improve their vegetation cover.
- According to the availability of the required data for the HEC-HMS model, it could be used to simulate rainfallrunoff processes in hydrologic studies of other basins.
- Such studies could be accelerated by using GIS combined with the HECHMS model.
- The Ministry of Jihad-e-Agriculture and Ministry of Energy of Iran can use the results of this study for planning
watershed and water resource management in Honam and Merek basins.
- Finally, it is suggested that measurements of precipitation, surface flow discharge, and the other parameters needed for simulation of rainfall-runoff behavior of the basin be continued. The model can then be run with more data to achieve more reasonable results for application in land use and flood management in these basins.

## Chapter 5.

## Drought Analysis in the Upper Karkheh River Basin

Jahangir Porhemmat, Sima Rahimi Bondarabadi and Tayeb Raziei

# Chapter 5: Drought Analysis in the Upper Karkheh River Basin 

Jahangir Porhemmat, Sima Rahimi Bondarabadi and Tayeb Raziei

### 5.1. Introduction

The Livelihood Resilience (LR) project proposal aimed at strengthening livelihood resilience through improved natural resource management in the Karkheh River Basin (KRB). Thus, knowledge of precipitation events and their temporal and spatial variations was important and necessary because precipitation is the most important component of water balance and its deficiency can lead to drought. In addition, precipitation plays an important role in the general climatic conditions and agricultural development. Amount and temporal distribution of precipitation are two significant factors in agricultural planning since they strongly affect soil moisture and availability of water resources for irrigation. Natural vegetation cover and rainfed crops are also controlled by the amount and temporal distribution of precipitation and its types. Since rainfed crops, livestock, and pastures are the main sources of income in the KRB, seasonal water deficit due to drought spells affects livelihoods of rural communities through impacts on agricultural production and natural vegetation in the rangelands. Therefore, drought analysis was included in the project studies. In this respect, since monthly drought analysis is needed for agricultural planning and the Standardized Precipitation Index (SPI) is an indicator of monthly conditions of this phenomenon, this index was selected for our analysis of drought in the KRB.

### 5.2. Drought and drought indices

Drought is a normal, recurrent feature of climate that may occur anywhere, although its characteristics and impacts vary significantly from region to region (Wilhite, 1997). It is defined as a natural temporary imbalance of water availability, consisting of a persistent lower-thanaverage precipitation, of uncertain frequency, duration and severity, of unpredictable or difficult to predict occurrence, resulting in diminished water resources availability and carrying capacity of the ecosystems (Pereira et al., 2002). Thus, an objective evaluation of drought conditions in a particular area is the first step for planning water resources in order to prevent and mitigate the negative impacts of future occurrences. For this purpose, several indices have been developed to evaluate water supply deficit in relation to the time duration of precipitation shortage (see Heim, 2002; Keyantash and Dracup, 2002 and references therein). Among them, the most commonly used for drought monitoring are the Palmer Drought Severity Index (PDSI; Palmer, 1965) and the SPI (McKee et al., 1993).

The PDSI is based on the supply-and-demand concept of the water balance equation for a two-layer soil model. It depends on several local coefficients that are estimated using local hydrological norms related to temperature and precipitation averaged over some calibration period (at least a 30-year period, according to the World Meteorological Organization recommendation). The basis of the index is the difference between the amount
of precipitation required to retain a normal water balance level and the actual precipitation. Nevertheless, if we wish to compare drought conditions of different areas, which often have different hydrological balances, the most important characteristic of any index is the standardization.

The SPI complies with this requirement. It is, in fact, a standardized index that can be computed on different time scales, thus allowing monitoring of most drought types, i.e. meteorological, agricultural, and hydrological. The SPI computation for any location is based on the long-term precipitation record cumulated over the selected time scale. This long-term record is fitted to a probability distribution (usually a Gamma distribution; Guttman, 1999), which is then transformed through an equal-probability transformation into a normal distribution. Positive SPI values indicate greater than median precipitation, and negative values indicate less than median precipitation (Bordi and Sutera, 2001). Thus, because the SPI is normalized, wetter and drier climates can be represented in the same way.

Guttman (1998) compared the Palmer Drought Index (an older version of the PDSI) with the SPI through a spectral analysis in order to evaluate the application accuracy. He recommended the SPI as a more useful drought index because it is standardized and contains a probabilistic interpretation, so it can be used in risk assessment and decision making. Paulo and Pereira (2006) compared the PDSI and the SPI, and concluded that the linear correlation coefficient between the two indices was higher for a 12-month time scale.

Morid et al. (2006) examined the performance of seven drought indices requiring only rainfall data for drought detection and monitoring in the Tehran Province of Iran. They concluded that,
despite different underlying statistical distributions, the SPI performed in a similar manner with regard to drought identification and drought onset, and that the SPI and Effective Drought Index (EDI) could be recommended for operational drought monitoring in the region. However, the EDI requires daily precipitation, which constitutes a serious limitation for its operational use. Thus, due to its advantages, the SPI appears to be the most powerful drought index.

Many authors (Hayes et al., 1999; Szalai et al., 2000; Bordi and Sutera, 2001; Lana et al., 2001; Lloyd-Hughes and Saunders, 2002; Tsakiris and Vangelis, 2004; Vicente-Serrano et al., 2004) have used the SPI to monitor drought in many regions, while others have used the SPI to predict drought class transitions adopting Markov-chain and log linear models (Paulo et al., 2005; Paulo and Pereira, 2007; Moreira et al., 2008), or to forecast drought with stochastic and neural networks modeling (Mishra and Desai, 2005).

### 5.3. The state of art of SPI

### 5.3.1. Selecting a suitable index for drought analysis

Accurate long-term climatic and hydrological data are necessary for studying drought events, and it is not possible to study drought processes without these data. Precipitation is the main factor in creation and controlling drought duration and intensity, but actual evapotranspiration is the most important factor in showing the effects of drought. The difficulties of evapotranspiration estimates have made precipitation the best and most accessible climatic parameter for computing drought indices.

In fact, the indices based on precipitation have had better results when comparing
to more complicated hydrological indices (Oladipio 1985). Among the indices based on precipitation, the SPI and Deciles Index have been widely accepted by scientific societies and users. In the present research, the SPI index is used for studying the drought phenomenon in the KRB.

### 5.3.2. Use of SPI

McKee et al. (1993) used SPI when they considered the effect of the precipitation deficit on groundwater, water supply sources, soil moisture, snow pack, and surface water relative to annual average. This index was designed for quantifying precipitation deficits over various time scales. In fact, these time scales declare the required times for the precipitation deficit impact on various water sources supply. The soil moisture condition reacts to short-term abnormality of precipitation, whereas groundwater, surface water, and water supply sources react to long-term abnormalities. Therefore, McKee et al. (1993) suggested the SPI for time scales of $3,6,12,24$, and 48 months.

Computation of SPI is based on longterm precipitation data and arbitrary time scales. These long-term data follow a probability distribution that can be transformed to a standard normal distribution in such a way that the data average equals zero in the arbitrary time intervals. Positive values of SPI represent higher than median precipitation, while negative values show the precipitation lower than the median. As the SPI index normalizes, drier or more humid weather can be explained through the same method.

McKee et al. (1993) used a classification system (Table 5.1) to describe drought severity as calculated by SPI. They also defined a drought criterion for each time interval. Hence, a drought event

Table 5.1. SPI values and related drought severity (Mckee et al., 1993).

| SPI values | Drought classification |
| :--- | :--- |
| $\geq 2$ | Extremely wet |
| 1.5 to 1.99 | Severely wet |
| 1 to 1.49 | Moderately wet |
| -0.99 to 0.99 | Mildly wet to mild drought |
| -1.49 to -1 | Moderate drought |
| -1.99 to -1.5 | Severe drought |
| $\leq-2$ | Extreme drought |

occurs when the negative SPI values are repeated and reach a severity below -1. Any drought event ceased when SPI approached a positive value. Therefore, every drought event had a duration, beginning, and ending time with a specific severity. Cumulative drought quantities which included a positive total SPI index in different months of a drought period were also considered as the drought amplitude and extension. This index has been used for drought monitoring for the state of Colorado since 1994 - and SPI-based drought maps of this state are prepared continuously for use by drought management planners.

### 5.3.3. Advantages of SPI

The SPI was first suggested by McKee et al. (1993). Computations of SPI are quite simple and the obtained results are reliable, especially in water resource studies. The SPI is only based on precipitation data and can be calculated in an arbitrary time scale. This ability enables study of water resource conditions in both short-term (best suited to agricultural studies on plant accessible moisture) and long-term time scales (important in the study of surface and groundwater resources). Another advantage of the SPI is that it can simultaneously be applied in the study of wet conditions. There are many research institutes in the USA that have
accepted SPI and are using it for drought and wet events monitoring. Turkey, Brazil, Mexico, Costa Rica, Argentina, Chile, Hungary, South Africa, and some European countries like Spain and Italy use the SPI for monitoring drought and wet conditions.

SPI computation needs a long-term monthly data: a minimum of a 30-year period of observation in any location. For computing SPI, first, the Probability Distribution Function (PDF) should be determined by fitting a proper probability function to the total data. Then, the Cumulative Distribution Function (CDF) should be transformed to a normal distribution of zero (0) average and standard deviation of one (1) by using the equivalent probability. Therefore, the estimated SPI is explained as a standard deviation unit.

The SPI is one of the most applicable indices in the study of drought and wet condition. Nowadays, the SPI is used all over the world and many scientific societies have accepted it. One of the most important advantages of this index is its flexibility in studying different types of drought.

Time scales shorter than six months are suitable for the study of agricultural droughts, while in studying impact of the seasonal precipitation changes on surface water resources, 6-10-month time scales are appropriate. A 12 -month time scale is used in the study of midterm changes and 18-months and longer time scales are applied in studies of hydrological and groundwater droughts. We can simply identify and study various drought and wet condition events and their characteristics in any arbitrary time scale using the SPI.

The results of much research have shown that the best PDF for the fitting of monthly precipitation data, especially
in arid and semiarid regions, is a Gamma function. McKee and many other researchers consider this distribution the best choice and so recommend it. Guttmann (1999) applied various statistical distributions to the data of different climatic regions of the USA and concluded that the Pierson Type 3 Function was the best fitted distribution and was applicable in most regions. He suggested this as an international model for the SPI. Lana et al. (2001) used SPI for the Catalonia region in the Iberian Peninsula and concluded that the Poisson-Gamma distribution was best for calculating this index.

Therefore, SPI estimates is a PDF fitting to a series of precipitation data for computing the probability and frequency of occurrence of any precipitation event based on that data set.
Then, the parameters related to this function are estimated for any time scale or months of the year and finally the related CDF will be calculated and transformed into a normal CDF for SPI calculation.

McKee et al. (1993) presented SPI classification values (Table 5.1) for analysis of the results and spatial comparison. As the computed SPI values have an almost equal fitting to a normal distribution, it is possible to assume that these values are within one unit of the standard deviation corresponding to $98 \%$ probability of occurrence and three units within 99\%. According to this classification, an extreme drought (SPI < -2) will occur two or three times in every 100 years. Therefore, one of the other advantages of this method is stating the return periods of SPI values, which are highly valuable in water resource management patterns and studies. As McKee et al. (1993) explained, the following reasons make the SPI the best choice in drought analysis (especially spatial analysis): (1) simple computation,
(2) availability of the required precipitation data, (3) applicability for any time scale, and (4) high efficiency in spatial comparison of the results.

Total precipitation for the various time scales of $1,3,6,9$, and 12 months can be assessed using the SPI in order to be used in different applications. The concept, calculation methods, and the application of any of these time scales are explained below:

## Three-month SPI

A three-month SPI time-series assesses and compares the precipitation amount of a three-month period of a specific year to the average precipitation of the same period in the whole statistical period under study. In other words, February three-month SPI compares the total precipitation of December-February for any year to the average precipitation of the same three months in the timeseries. A three-month SPI demonstrates humidity and wet conditions of a region in the short-term and medium-term. Therefore, it is a good criterion to assess seasonal humidity of a region. As a result, the three-month SPI is an appropriate index for agricultural drought assessment. This index is very sensitive and reacts to even trivial precipitation fluctuation.

## Six-month SPI

A six-month SPI time-series assesses and compares the precipitation amount of a six-month period of a specific year to the average precipitation of the same period in the whole statistical period under study. For example, sixmonth SPI of September 2000 in a sixmonth time scale compares the total amount of precipitation in September and the previous five months (AprilSeptember) to the average amount of precipitation in the long-term. This time
scale demonstrates the medium-term changes in precipitation and is sensitive to seasonal changes of precipitation and so is a good criterion for investigating total precipitation and water potential of a region in different seasons. Due to the sensitivity of this time scale to precipitation changes that are effective in the discharge of dams and rivers, one can easily forecast and estimate the water level of rivers and discharge and, also, the future water potential of the region.

## Nine-month SPI

Like six-month SPI, a nine-month timeseries assesses and compares the precipitation amount of a nine-month period in any specific year to the average long-term precipitation of that period. This time scale shows long-term changes in precipitation and is an appropriate criterion in the assessment of seasonal and annual changes of precipitation that are effective in the water supply of dams, surface waters, and rivers.

## 12-month SPI

A 12-month SPI assesses and compares the precipitation amount of any 12 successive months in any specific year to the average long-term precipitation of that period. This time scale is an intermediate scale between shortand long-term. A 12-month SPI of February compares the total amount of precipitation in February and the previous 11 months to the average amount of the long-term precipitation in this period, which is the sum of precipitation from March 1999 to the end of February 2000. This time-scale analysis shows hydrologic droughts. Such a scale could show the long-period droughts that decrease river flow, or cause drawdown of reservoir water levels or groundwater tables. Investigations in the USA show that the result of this time scale is similar to the Palmer method, and thus SPI and PDSI have a high correlation with each other.

Therefore, SPI analysis can determine severe meteorological and hydrological droughts.

### 5.4. Methodology

The methodology was based on the method of McKee et al. (1993). Accordingly, the probability distribution of rainfall time-series and the best fitted distributions were investigated. Results showed that some of the time-series did not fit the distribution, because of many zero values in the series and high skewness of the data. This condition was observed especially when the time scale for calculating the criterion was less than three months. For example, the sum of summer rainfall in some of the stations was often zero; however, in longer time scales the probability distribution of the data tends to normal. Thus, SPI in longer time scales are more significant.

In this study, 1, 3, 6 and 12-month SPIs were used to evaluate hydrological and agricultural droughts in the study area, although one-month SPI was used whenever possible. To this end, we first established the Gamma distribution as the best distribution for the data. Then, the fitted Gamma distribution was transformed to a normal distribution and SPI values were calculated for 1 , 3, 6 and 12-month scales. Drought was determined in the threshold SPI value of - 1 in the stations. Characteristics such as mean, maximum, and minimum of drought severity were calculated.

Selection of a suitable statistical time period is very important in studying drought. The longer the length of this period, the more accurate are the results, and the better can long periods of a few years of drought be identified. However, selection of long time periods will eliminate use of stations with short-term data and so reduce the resolution of the
study stations. Therefore, it is necessary to fulfill the requirement of a suitable resolution of stations and the length of the statistical period for the study. Consequently, information from stations with long-term records was used to study drought in the KRB.

Monthly precipitation data for 45 stations in the region were obtained from the Iranian Water Resources Institute and the Iranian Meteorological Organization (Appendix II). The randomness of the annual data sets was investigated through tests for homogeneity, absence of artificial trends, and spurious autocorrelation. Following Helsel and Hirsch (1992), a set of non-parametric tests was applied: the Mann-Whitney homogeneity test, the Mann-Kendall trend test, and the Kendall's $\tau$ autocorrelation test. These tests were performed for all stations as described by Paulo et al. (2003) using software developed by Matias (1998). The test results led to discarding of 17 stations with low quality data or $>5 \%$ of missing values. The remaining 28 stations covered 35 hydrological years, from October 1965 to September 2000, and constituted a well-distributed network throughout the study area (Figure 5.1). Missing values for each station were estimated using the Move4 technique (Maintenance of Variance Extension), which developed a linear equation such that a reasonable and unique extended record was generated, while maintaining the variance of the data series unchanged (Vogel and Stedinger, 1985). Tables 5.2, 5.3 and Appendix II show the time-series of rainfall in the KRB.

For evaluation of drought in Merek and Honam watersheds, the two selected catchments in the KRB, the nearby stations of Kermanshah and Alashtar were used. Regional drought characteristics were studied in the entire KRB.

Figure 5.1. Location of meteorological stations in the upper KRB.

The main specifications of drought events are duration, intensity, and magnitude. In drought research, study of these specifications is very important. Frequency or probability of occurrence and maximum intensity are the other specifications of drought. Considering that every long-term drought is not necessarily the most intensive and hazardous drought event, the importance of studying these specifications becomes clear. Therefore, other parameters of droughts such as starting time, mean and maximum intensity, and magnitude should be considered along with drought duration. According to Yevjevich (1967), the amount of negative deviation of the index (SPI in this case) from its mean value or any other selected truncation level measures the severity of drought. The number of consecutive intervals where the index has lower values than the truncated level (e.g. zero value in the SPI index) indicates the drought duration. The sum of deviations between
the truncation level and the index values along a deficit run (a drought event) represents the total deficit amount or drought magnitude for that event. Moreover, by dividing the magnitude of the considered drought event to its duration, the drought intensity can be easily obtained.

Intensity and duration are the two main specifications of drought. Degree of hardness or impact value of a drought is described based on these specifications. The greater the intensity (mean deviation of drought index in the drought period) and duration of a drought event, the higher will be its negative effects.

SPI time-series of Kermanshah and Alashtar stations (Appendix III), as two KRB representative stations, were used to analyze the temporal variations of drought. Figures 5.2 to 5.5 show graphs of 1, 3, 6 and 12-month SPIs for Alashtar station: SPI variations of the longer time

Figure 5.2. One-month SPI time-series for Alashtar station.

scales were less than those of one- and three-month values, in comparison with the mean. Therefore, six- and 12-month SPIs are suitable for determination of drought characteristics. Notably, these figures show some of the main drought spells of 1970, 1983-1985, 1999, and 2000. Similarly, Figures 5.6 to 5.9 shows SPI time-series of Kermanshah Station. In Merek catchment, based on threemonth SPI, drought events occurred in 1978, 1984, 1991, 1995, 1999, and 2000; while for Alashtar, based on sixmonth SPI, the drought years were 1974, 1979-1980, 1984, 1991, 1996, 1999, and 2000. Comparison of the drought years showed that 1999 and 2000 were common to both catchments.

### 5.5. Results in Honam and Merek

To study the specifications of droughts, all drought events in each station were considered. Table 5.2 shows the number of drought events of the two catchments identified using SPI-3. Most of the drought events in the catchments were of 1-3 months type and with a longer duration, the less was the number of drought events. For this time scale in the study period, both catchments experienced 14-20 droughts of 1-3 months duration (Table 5.2). Also, time scales of 4-6-months, up to some extent, showed a considerable number of drought events. However, the number of drought

Table 5.2. Characteristics of droughts in Honam (Alashtar station) and Merek (Kermanshah station) catchments.

| Duration (months) | Magnitude | Mean severity | Max severity | Min severity | No. of drought events |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Honam (Alashtar station) |  |  |  |  |  |
| 1 | -10.18 | -0.73 | -0.56 | -1.51 | 14 |
| 2 | -11.8 | -0.84 | -0.57 | -1.3 | 7 |
| 3 | -22.44 | -0.93 | -0.52 | -1.93 | 8 |
| 4 | -14.76 | -1.23 | -0.57 | -2.25 | 3 |
| 5 | -4.01 | -0.8 | -0.57 | -1.24 | 1 |

| 8 | ...... | ...... | ...... | ...... | ...... |
| 9 | -10.90 | -1.21 | -0.55 | -1.95 | 1 |

events with a six-month time period was quite limited.

Mean severity of drought in Honam was from a minimum of -0.7 with duration of one month to -1.7 with a duration of nine months. The corresponding values in Merek were -0.9 and -1.3 , with durations of one and six months, respectively. In general, in both catchments, the magnitude of drought of three months were greater than for other time scales.

### 5.6. Spatial analysis of climatological drought

SPI maps of September of different years, showing the sum of rainfall of September and the prior 11 months (data not presented), were used to study spatial distribution of drought and highcoverage dry periods in the region. These showed that extensive areas of the KRB experienced mild to severe droughts in 1967, 1970, 1973, 1979, 1980, 1982, 1983, 1984, 1985, 1989, 1991, 1997, 1999, and 2000.

During these years, Merek and Honam catchments also experienced drought periods of different intensities. In 1970, there was no drought in either catchment. In 1973, 1979, and 1982, only Merek experienced drought and in 1985, 1997, and 2000, the intensity of drought in Merek was greater than in Honam. In 1983, 1985, and 1991, the intensity of drought in Honam was high. In 1980, only Honam experienced drought.

Considering the agricultural and rainfall season of the region, spatial distribution maps of one-month SPI were plotted for April, May, October, and November during 1966-2000 (data not presented). The maps for these four months showed that, in general, drought was more frequent in Merek. Table 5.3 shows the years with drought during one or more of the aforementioned four months in the studied catchments.

During 1966-2000, there was no drought in Honam in October, whereas Merek experienced drought 11 times in that month (Table 5.3). In November, the

| Merek |  | Honam |  |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| May | Apr. | Nov. | Oct. | May | Apr. | Nov. | Oct. |
| 1970 | 1978 | 1966 | 1973 | 1973 | 1978 | 1966 | $\ldots . . .$. |
| 1973 | 1979 | 1973 | 1974 | 1974 | 1979 | 1969 | $\ldots . . .$. |
| 1974 | 1980 | 1976 | 1975 | 1978 | 1984 | 1976 | $\ldots \ldots .$. |
| 1980 | 1989 | 1978 | 1978 | 1984 | 1985 | 1978 | $\ldots \ldots .$. |
| 1984 | 1991 | 1979 | 1983 | 1987 | 1987 | 1982 | $\ldots \ldots .$. |
| 1987 | 1999 | 1988 | 1985 | 1991 | 1989 | 1983 | $\ldots \ldots .$. |
| 1988 | 2000 | 1990 | 1989 | 1999 | 1991 | 1988 | $\ldots \ldots .$. |
| 1990 |  | 1995 | 1992 | 2000 | 1999 | 1995 | $\ldots \ldots .$. |
| 1991 |  | 1996 | 1995 |  | 2000 | 1996 | $\ldots . . .$. |
| 1994 |  |  | 1996 |  |  |  | $\ldots . . .$. |
| 1998 |  |  | 1998 |  |  |  | $\ldots . . . .$. |

two catchments suffered very similar droughts, often at the same time. Also, in both catchments, the frequency of drought in April was almost the same. In different years, drought in May was more frequent in Merek than Honam, although in some years both catchments experienced drought.

To study the frequency of droughts in these four months, the probability of occurrence of SPIs smaller than -1 was determined using the Weibull method and the map of their spatial distribution for the region was extracted.

## Benchmark river basins

The CP Water \& Food is a research, extension and capacity building program aims at increasing the productivity of water used for agriculture. The CP Water \& Food is managed by an 18-member consortium, composed of five CGIAR/Future Harvest Centres, six National Agricultural Research and Extension Systems (NARES) institutions, four Advanced Research Institutes (ARIs) and three international NGOs. The project is implemented at nine river basins (shown above) across the developing world. The Karkheh River Basin (KRB) in western Iran is one of the selected basins. The program's interlocking goals are to allow more food to be produced with the same amount of water that is used in agriculture today, as populations expand over the coming twenty years. And, do this in a way that decreases malnourishment and rural poverty, improves people's health and maintains environmental sustainability.

Improving On-farm Agricultural Water Productivity in the Karkheh River Basin Project (CPWF PN 8)
Strengthening Livelihood Resilience in Upper Catchments of Dry Areas by Integrated NRM (CPWF PN 24)
